The cause of the mass extinctions in the past have been revealed with the aid of nuclear dating techniques. One of the recent examples is the 2nd largest extinction event; namely, the Ordovician-Silurian extinction. Widespread marine anoxia is hypothesized as the trigger for the second pulse of the Late Ordovician (Hirnantian) mass extinction, based on lithologic and geochemical proxies that recorded the redox level of local bottom waters or porewaters. In the ocean, $^{238}\text{U(IV)}$ is preferentially sequestered into anoxic marine sediments, leaving the residual U(VI) in seawater with a lower $^{238}\text{U}/^{235}\text{U}$ ratio, which is subsequently incorporated into carbonate sediments. The isotope ratio is often given as the relative ratio against that of standard material (Eq. 9).

$$\delta^{238}\text{U} = \left[\left(^{238}\text{U}/^{235}\text{U} \right)_{\text{sample}} / \left(^{238}\text{U}/^{235}\text{U} \right)_{\text{standard}} - 1 \right] \times 1000 \quad (9)$$

Therefore, $\delta^{238}\text{U}$ values can serve as a proxy for global-ocean redox conditions and provide a means of quantifying changes in the extent of anoxic sediment accumulation across a range of geologic time intervals. Bartlett et al. (2018) constructed a steady-state model under the assumptions (1) constant U isotopic composition of the riverine source (modern $\delta^{138}\text{U}$ river as -0.29‰), (2) constant fractionation factors for oxic/suboxic and anoxic/euxinic sinks (0.77‰), (3) constant U burial rates, and (4) constant diagenetic correction factor to account for ^{238}U enrichment during the formation of cement phases in O_2 -depleted porewaters (0.2‰). Bartlett et al.'s model shows that during the Hirnantian ocean anoxic event, there was a $\sim 15\%$ increase in anoxic seafloor area, and $\sim 80\%$ of seawater U was sequestered into anoxic sediments.

Great Ocean Conveyor Belt

Unlike the wind driven ocean currents that move with a maximum speed of an order of hundreds of cm/s in the upper few hundred meters of the ocean (e.g., Gulf Stream, Dong et al., 2019), the conveyor belt (Fig. 6) moves horizontally in the order of a few cm/s (e.g., Richardson, 2008) and vertically in the order of about 10^{-5} to 10^{-3} cm/s (Liang et al., 2017). Any direct currently available ocean current measurement methods, e.g., mechanical, electromagnetic, or acoustic meters, have measurement errors larger than a few cm/s (e.g., Guerra and Thomson, 2017). Hence, they are rarely applicable in the deep sea where the suspended particulate matter is extremely low (in the order of less than a few tens of $\mu\text{g/L}$). The apparent simple question, posed at a particular location of the sea, “what is the vertical mixing rate? and what is the age of deep water?” becomes much more complex to answer using direct measurement methods. Radionuclides present in the ocean, with known input function and half-lives along with modeling, fill this gap to measuring slow but important climate processes occurring in the ocean (Jenkins, 2003). Thanks to radionuclides quantitative information, such as rates and fluxes of energy and material, we can now better understand the ocean and are able to predict the future climate change.

The Great Ocean Conveyor Belt, termed by Broecker (1991, 2010), or the Atlantic meridional overturning circulation (AMOC), or sometimes, thermohaline circulation (THC), is the major mechanism by which the ocean redistributes heat over the globe. Significant changes in the Great Ocean Conveyor Belt will, therefore, affect the global radiation balance through altering the atmosphere's surface boundary conditions, and hence, lead to major climate change (Richardson, 2008). Broecker (1991) succinctly explained it based on the paleo air temperature inferred from the oxygen isotopes ($^{18}\text{O}/^{16}\text{O}$) record preserved in the Greenland

ice cap and radiocarbon ^{14}C -based estimate of the flux of the North Atlantic Deep Water among others, in plain language as following: “The ocean’s conveyor appears to be driven by the salt behind as the result of water-vapor transport through the atmosphere from the Atlantic to the Pacific basin. A byproduct of its operation is the heat that maintains the anomalously warm winter air temperatures enjoyed by northern Europe. A millennium of very cold conditions known as the Younger Dryas (around 12,900 to 11,700 years ago) appears to have been the result of temporary shutdown the conveyor.”

It is estimated that any given cubic meter of water takes about 600–1000 years to complete the journey along the great ocean conveyor. This movement consists of an immense volume of water, $17.0 \pm 4.4 \text{ Sv}$ ($1 \text{ Sv} = 1.0 \times 10^6 \text{ m}^3 \text{ s}^{-1}$), with seasonal and interannual variations (Frajka-Williams et al., 2019). This volume of water is about 15 times greater than all world river discharge combined (1.14 Sv , Suzuki et al., 2018). Therefore, any changes in the global ocean conveyor belt would bring drastic changes in our climate—as happened in the past. For example, if its slowdown since the middle of the last century continues, Europe will be much colder in winter and hotter in summer, along with increased iceberg streams in the North America as in the past 12.9 and 11.6 thousand years (Bromley et al., 2018).

On the other hand, in the glacial period, the ocean conveyor belt moved faster and stronger as evidenced from high resolution sedimentary records of $^{231}\text{Pa}/^{230}\text{Th}$ and $^{143}\text{Nd}/^{144}\text{Nd}$ in the deep western North Atlantic (Böhm et al., 2015). The isotopes ^{231}Pa ($t_{1/2} = 3.25 \times 10^4$ years) and ^{230}Th ($t_{1/2} = 7.52 \times 10^4$ years) are produced in the ocean at constant rates by radioactive decay of ^{235}U and ^{238}U , respectively. They have remained in the ocean for about 20 to 40 years and about 100–200 years (e.g., Yu et al., 1996), respectively, and both have exhibited high particle affinity. In the well-ventilated N Atlantic, the activity ratio of $^{231}\text{Pa}/^{230}\text{Th}$ in recently sedimented particles is low (0.093), as approximately half of ^{231}Pa produced in the North Atlantic is exported to the Southern Ocean where it is scavenged out in the high-opal (SiO_2) flux region. In the simplest terms, a slowdown of Atlantic meridional overturning (Great Ocean Conveyor Belt) should result in less ^{231}Pa exported to the Southern Ocean and, thus, higher Atlantic $^{231}\text{Pa}/^{230}\text{Th}$ ratios (Bradtmeier et al., 2014). ^{143}Nd ($t_{1/2} = 1.06 \times 10^{11}$ years) is produced from primordial ^{147}Sm ($t_{1/2} = 1.06 \times 10^{11}$ years), and ^{144}Nd ($t_{1/2} = 7 \times 10^5$ years) is produced from primordial ^{148}Sm ($t_{1/2} = 7 \times 10^{15}$ years). The Nd isotope ratio is expressed usually as $\epsilon_{\text{Nd}} = ((^{143}\text{Nd}/^{144}\text{Nd})/0.512638) - 1 \times 10^4$, where 0.512638 is a present day average Earth value ($^{143}\text{Nd}/^{144}\text{Nd}$) of the Chondritic Uniform Reservoir (CHUR) (Bizimis and Scher, 2016; Huang et al., 2012). The gradual ϵ_{Nd} increase has occurred for intermediate and deep-water masses from the northwest North Atlantic ($\epsilon_{\text{Nd}} < -13$), via the Southern and Indian oceans to the Pacific ($\epsilon_{\text{Nd}} < -3$), relative to the low ϵ_{Nd} in the North Atlantic being surrounded by old, highly unradiogenic crustal rocks, while the Pacific is surrounded by younger volcanic systems with contributions from the depleted mantle. These seawater ϵ_{Nd} values are recorded in fossil fish debris, deep-sea coral skeletons, and ferromanganese nodules, and coatings on bulk sediment particles, or inside foraminiferal calcite tests. These archived time series data reveal the strengthening or relaxation of Great Ocean Conveyor Belt.

Besides the above-mentioned application of radionuclides in investigating slow oceanic processes or oceanic processes too difficult to measure directly, Broecker and Peng (1982) illustrated succinctly that many natural and anthropogenic radionuclides have been used in the ocean studies, such as rate of gas exchange at sea-air interface (e.g., ^{14}C , ^{222}Ra), particle formation, sinking, and accumulation at the sea floor (e.g., $^{234}\text{Th}/^{238}\text{U}$, $^{228}\text{Th}/^{228}\text{Ra}$, $^{230}\text{Th}/^{234}\text{U}$, $^{231}\text{Pa}/^{235}\text{U}$, $^{210}\text{Pb}/^{226}\text{Ra}$, $^{210}\text{Po}/^{210}\text{Pb}$, ^{14}C), the rate of vertical mixing of ocean (^{14}C), dating of sediment core layers and coral growth bands (^{14}C , excess ^{230}Th , ^{10}Be , ^{40}K , ^{40}Ar), efflux of hydrothermal fluid from underwater volcano (^3He), photosynthesis and respiration ($^{13}\text{C}/^{12}\text{C}$), diapycnal and isopycnal water mixing and vertical diffusivity coefficient (^{222}Rn , ^{228}Ra), and downwelling (deep water formation or ventilation of deep ocean) (^{14}C , ^{39}Ar). Radium radionuclides of ^{223}Ra , ^{224}Ra , ^{226}Ra , and ^{228}Ra are also proven to be useful to trace and quantify submarine groundwater discharge in coastal waters (e.g., Moore, 2006; Povinec et al., 2008c). More recently, a coordinated international program to systemically study the marine biogeochemical cycles of trace elements and their isotopes to cover the global oceans is now underway. This study, under the name of the GEOTRACES program, should expand our ability to decipher climate and environmental changes occurring in our time (Anderson, 2020). It is scheduled for completion by the end of this decade.

Developments in radioanalytical technologies

Earlier analytical methods in marine radioactivity involved collection of relatively large volumes of water (often more than 100 L, e.g., Fonselius and Östlund, 1959; Bowen et al., 1980) followed by preconcentration, radiochemical processing and measurements following radioactive decays using alpha, beta and gamma ray spectrometers, or using mass spectrometry for long-lived radionuclides (Povinec et al., 2008a, 2020; Levy et al., 2011). New developments in instrumentation, and technology in sample collection, preconcentration, and analysis have reduced the sample size as well as the time involved in processing and measurement of samples for anthropogenic radionuclides (Baskaran et al., 2009). All the developments in marine radioactivity studies have been possible due to new radioanalytical technologies, which have considerably improved the sensitivity of radionuclide analyses. Many marine radioactivity studies were not possible to carry out before, either because of lack of sensitivity or requirements of large volume samples. There is no space available to go into details. Therefore, we mention only a few developments and their applications (Povinec, 2018a,b).

The first break-through in radiometric techniques for analysis of environmental radionuclides at very low-levels (down to $\mu\text{Bq/kg}$ scale) has been the development of large volume HPGe detectors and their operation in underground laboratories (e.g., Laubenstein et al., 2004; Povinec et al., 2004, 2005, 2008a, 2013b, 2020; Aoyama et al., 2011a,b; Levy et al., 2011). Semiconductor alpha-ray spectrometry and liquid scintillation spectrometry remain powerful techniques for the analysis of alpha- and beta-emitters because of the simplicity of measurement, reasonable resolution and high sensitivity (Aoyama and Hirose, 2004; La Rosa et al., 2005; Lee et al., 2001; Levy et al., 2011). It is expected that the radiometrics sector will dominate also in future in the analysis of short- and medium-lived radionuclides (Povinec et al., 2020).

Specific radiometric developments included in situ gamma-ray spectrometers to be applied in mapping radionuclide distributions in seawater and sediments. Underwater gamma-ray spectrometry has been widely applied for studies of both spatial and temporal variations of gamma-ray emitters in the marine environment, sometimes working with satellite data transmission from the field to the laboratory, specifically when large sea surfaces should be scanned, or continuous monitoring should be carried out (Povinec et al., 1997, 1999, 2008b; Osvath et al., 2001, 2005), including the investigation of submarine discharges to the sea (Povinec et al., 2008a,c,d, 2020).

The most exciting breakthrough in the analysis of long-lived radionuclides in the marine environment has been made by the development of accelerator mass spectrometry (AMS), which offers the best sensitivity, requires minimum sample size, and minimizes matrix and interference effects (Povinec et al., 2008a, 2009). A direct coupling of accelerators with chromatographs has enabled researchers to proceed from a bulk sample analysis to a compound specific analysis, even to single atom counting (e.g., Povinec et al., 2009, 2020).

We list here at least two interesting applications: (1) new radioanalytical technologies have helped develop the analysis of a small volume of water samples; for example ^3H , ^{14}C , and ^{137}Cs (the first data sets with analysis of 10–20 L water samples) deep water mapping of the Pacific Ocean (Aoyama et al., 2011a,b; Povinec et al., 2011a; Kumamoto et al., 2011), and (2) the transport of north Pacific waters through the Equator (Aoyama et al., 2011a,b), which have been an important prerequisite for later studies of the FDNPP accident impacts. In the Indian Ocean, deep water mapping indicated the accumulation of ^3H and ^{14}C within the Subtropical gyre, confirming that the south Indian Ocean has been acting on a time scale of several decades as a final reservoir of contaminants transported from the northern Indian and Pacific Oceans (Povinec et al., 2011a,b). The ^{14}C water profile data clearly showed a penetration of bomb fallout ^{14}C down to almost 5000 m, documenting that the south Indian Ocean is an important sink for anthropogenic carbon. If we accept that the world ocean generally controls the climate on the Earth, then the Indian Ocean in this respect is playing a crucial role.

Certified reference materials for radionuclides in seawater, sediment, and marine biota has proved to be a must in quality assurance and quality control of radionuclide analyses (e.g. Povinec and Pham, 2001; Povinec et al., 2002, 2007; Pham et al., 2006a,b, 2008, 2010a,b, 2014, 2016). Similarly, a great impact on the marine radioactivity studies has been due to the development of marine radioactivity databases, e.g. HAM database (Aoyama and Hirose, 2004), and the IAEA's MARIS database (<https://maris.iaea.org/home>) (Povinec et al., 2006, 2020).

Conclusions

The ecosystem contributions of the global oceans have been increasing continuously by the aid of advancements of scientific knowledge. Oceans are becoming recognized as indispensable habitats for the entire human race. Advancements in nuclear science and technology have greatly increased our knowledge in understanding the evolution of the earth and environmental changes that have occurred in the ocean from the beginning. Hence, climate change is now and will be better understood than ever. Many questions related to the climate and marine environmental change are being addressed using radionuclides as tracers by employing new analytical methods and technologies. Scientific understanding on the underlying climate change and measurement capabilities will enable us to manage our ocean more robustly in a sustainable manner.

Introduction

The term “natural capital” is now widely accepted as it provides a way of thinking about nature as a stock that provides a flow of benefit to people and the economy. The stocks of natural assets refer to the living and non-living components of ecosystems. Multiple forms of natural capital interact to generate goods and services (Guerry et al., 2015). Nearly 2.4 billion people (about 40% of the world’s population) live within 100 km of the coast (UN, 2017), and many coastal inhabitants draw their livelihood directly from the coast and coastal ocean. Coastal oceans consisting of tidal marsh, mangroves, estuaries, seagrass, macroalgal beds, coral reefs, and continental shelf, covering 32×10^6 km² (equivalent to approximately 9% of the ocean surface), provided 28 trillion US dollars’ worth of services to the human society (at 2007 \$US value) in 2011. The ecosystem service of the global oceans amounted to about 50 trillion US dollars per year (at 2007 \$US value) and accounts for about 40% of the global total value of ecosystem services in 2011 (Costanza et al., 2014). Marine transportation handles about 11 billion tons of cargo and provides more than 80% of global trade by volume (UNCTAD, 2020).

The US Ocean alone produces \$282 billion in goods and services annually according to the various government sources (NOAA, 2020). Without the oceans, human survival and their civilization may not have been sustainable. The ocean natural capital has increased almost twofolds over between 1997 and 2011 (Costanza et al., 2014), and will continue to increase as more scientific investigation reveals its value and as more innovative engineering projects working with nature allow us to use more ocean space and previously untapped ocean resources. For example, the effect of the damping impact of storm surges and strong winds by coastal wetlands recently was estimated to be $\$1.8 \times 10^6$ /km² per year in the United States, and property damage due to recent wetland losses at the time of Hurricane Irma was found to incur as much as \$430 million dollars (Sun and Carson, 2020).

The meaning of marine pollution covers more broadly than mere chemical pollution that is usually referred in the terrestrial environments. The International Environmental Treaty defines marine pollution as “the introduction, directly or indirectly, by human activity, of wastes or other matter into the sea which results or is likely to result in such deleterious effects as harm to living resources and marine ecosystems, hazards to human health, hindrance to marine activities, including fishing and other legitimate uses of the sea, impairment of quality for use of sea water and reduction of amenities” (Article 1.10, 1996 Protocol to the Convention on the Prevention of Marine Pollution by Dumping of Wastes and Other Matter, 1972).

Radioactive substance poses two kinds of threat to the marine environment: radiation and the chemical toxicity. Due to the legacy of the enormous damage having arisen from nuclear weapon blasts, regardless of the amount of radiation doses stemming from the released radioactive substances into the marine environment, any accidental release of radioactive substance into the marine environment will significantly curtail many legitimate uses of the sea. These include fishing activities, marine ecosystem service, recreational activities, and tourism industry by forcing people to avoid visiting oceans and consuming fisheries products, as we observed during the initial stage of the aftermath of Fukushima accident (e.g., Fukumo, 2020).

Radionuclides have been released to the environment from various sources, both planned and accidental. They include global nuclear weapons fallout (largest by far), the Chernobyl accident, the Fukushima accident, controlled releases from Sellafield and Cap de la Hague reprocessing plants, sea dumping of radioactive wastes, river runoff of previously deposited radionuclides on land surface and from the inland nuclear facilities, and loss or accidents involving nuclear materials (weapons, nuclear submarines, satellite fuels, and thermoelectric generators for lighthouse or ocean buoys; IAEA, 1999, 2001; Livingston and Povinec, 2000; Hong et al., 2004). Due to the global fallout through the stratosphere, the entire surface of the earth has been contaminated with radioactive debris in the early 1960s.

The IAEA has compiled global ocean anthropogenic radionuclides activity concentrations since 1961. As part of their effort, a coordinated research project yielded a final report on the worldwide marine radioactivity studies in 2005, which is the most recent one (IAEA, 2005; Povinec et al., 2005). According to their report, the total ^{137}Cs input from global fallout was estimated to be 311 PBq for the Pacific Ocean, 201 PBq for the Atlantic Ocean, 84 PBq for the Indian Ocean, and 7.4 PBq for the Arctic Ocean. For comparison, about 40 PBq of ^{137}Cs was released to the marine environment from the Sellafield and Cap de la Hague reprocessing plants. The Chernobyl accident contributed about 16 PBq of ^{137}Cs to the sea, mainly the Baltic and Black Seas, where the present average concentrations of ^{137}Cs in surface water were estimated to be about 60 and 25 Bq/m³, respectively, while the worldwide average concentration due to global fallout is about 2 Bq/m³. Therefore, global fallout has been considered as the largest input to the ocean (IAEA, 2005).

Testing of nuclear weapons fallout in the air or at the surface

According to the Comprehensive Nuclear Test Ban Treaty Organization (CTBTO), the rapid, uncontrolled reactions involved in testing of weapons in the air (1945–1980 by the United States, USSR, United Kingdom, France, China) released radioactive fallout all over the surface (Fig. 1). Globally, there have been at least 423 nuclear weapons tests with a substantial amount of radioactive fallout between 1945 and 1980 (Hamilton et al., 1996) and over 2000 nuclear explosions were reported from 1945 to 1996. Since 1996, nuclear weapon tests were also conducted from India, Pakistan in 1996, and the Democratic People’s Republic of Korea in 2006–17 (CTBTO, 2020). The explosion of nuclear weapons in the stratosphere and troposphere resulted in the release of radioactive debris in the air and these airborne radioactive materials were gradually deposited on the surface of the earth, including oceans, within a few years (Comar, 1963).

Although the solubility of the debris is sensitive to the composition of the explosion environment, air explosions produce small particles with high water solubility (UNSCEAR, 1962). The explosion of nuclear weapons at the surface generated radioactive debris that is subject to be transported by the prevailing winds, often divided into separate radioactive cloud where there is a steep wind speed gradient with altitude. In the stratosphere, zonal winds distribute radio-active debris in a latitudinal band of the stratosphere circling the earth within a few days to 6 weeks after the injection (Machta et al., 1956; Bleeker, 1961; UNSCEAR, 1962). The fear of environmental contamination as the result of nuclear fallout convinced the international community to adopt the Treaty Banning Nuclear Weapons Tests in the Atmosphere, in Outer Space and Underwater in 1963, followed by moratoria by the United Kingdom, the United States and the USSR, although the Chinese tested nuclear weapons from 1964 to 1980 in the air. Later the Comprehensive Test Ban Treaty (CTBT) was signed in 1996 (Bergkvist and Ferm, 2000). Therefore, the possibility of the global fallout from the nuclear weapon testing appears to be largely eliminated for now, although undeclared nuclear tests have been carried out by some countries, but mostly underground.

Unlike terrestrial environments, although the source term is still important, the mixing and transport of waterborne radionuclides in the world’s oceans and seas over time became significantly redistributed over the vast ocean areas, as well as sinking to the bottom and becoming entrained in the settling particulate matter and biological organisms. Therefore, the marine environment labelled with radionuclides differs from one region to another (e.g., Povinec et al., 2005; Fig. 2), and their activity concentrations continue to evolve with time—especially for the long-lived radionuclides relative to the time of water renewal.

The largest ocean, the Pacific, has been a major repository for these releases for at least three reasons: (1) partly because of its sheer size, (2) due to its proximity to releases such as the fallout in Bikini and Eniwetok Atolls in Marshall Islands, and now from the FDNPP accident, and (3) due to the nature of the end of the deep ocean conveyor belt that has about 600–1000 years of turnaround time (Livingston and Povinec, 2002). Therefore, the deep waters of the North Pacific Ocean will continue to

Fig. 1 ^{90}Sr and ^{137}Cs monthly deposition observed at the Meteorological Research Institute at Koenji Tokyo (35.7079° N, 139.6465° E, 1957–80) and at Tsukuba (36.0835° N, 140.0764° E, since 1981). Monthly deposition is expressed in millibecquerel per square meter on a logarithmic scale. The effects of atmospheric nuclear bomb tests have been recorded since 1957. Until the Partial Test Ban Treaty (PTBT) became effective in 1963, the United States, Soviet Union, and United Kingdom conducted atmospheric tests. France and China continued atmospheric testing until 1974 and 1980, respectively. The downward trend was interrupted by two excursion events, the Chernobyl accident in 1986 and Fukushima Daiichi Nuclear Power Plant (FDNPP) accident in 2011. The total amount of ^{90}Sr and ^{137}Cs deposition from 1957 to 2010 was compared to the FDNPP-derived deposition. Igarashi Y, Kajino M, Zaizen Y, Adachi K, and Mikami M (2015) Atmospheric radioactivity over Tsukuba, Japan: As summary of three years of observations after the FDNPP accident. *Progress in Earth and Planetary Science* 2: 44. <https://doi.org/10.1186/s40645-015-0066-1>.

Fig. 2 Activity concentration of ^{137}Cs (adjusted to the year of 2000) in the world's oceans and seas. IAEA (2005) *Worldwide Marine Radioactivity Studies (WOMARS). Radionuclide Levels in Oceans and Seas*. IAEA-TECDOC-1429. Vienna: International Atomic Energy Agency, 197 p.

accumulate anthropogenic radionuclides over the centuries (Fig. 3). More than 80% of the total $^{239} + ^{240}\text{Pu}$ inventory originated from weapons testing are remains in the water column (Hamilton et al., 1996).

Nuclear power plants

Various forms of energy, such as coal, oil, natural gas, biomass, hydropower, wind, geothermal, and solar energies have been explored and exploited in the developmental course of human civilization. Nuclear energy was introduced for the first time as

Fig. 3 A time series vertical profiles of the total $^{239}+^{240}\text{Pu}$ (dpm/100 kg) in the northwest Pacific Ocean from the year of 1973 to 1997. G223 (34.9667°N 151.8333°E), G224 (34.15°N, 141.9667°E), G225 (32.61667°N 161.9167°E), G226 (30.5667°N 170.6333°E) were sampled in 1973 (Ostlund et al., 1987), KH80-5 (40.0333°N 156.0333°E), KH80-6 (39.05°N 166°E), KH 80-8 (38.05°N 179.7167°E), KH80-11 (30.56667°N 170.6667°E) were sampled in 1980, KH 82-5 (25.0333°N 169.9833°E) was sampled in 1982 (Nagaya and Nakamura, 1984, 1984), and 97-1-1 (34.9983°N 145.9983°E) and 97-1-3 (30.5633°N 170.615°E) were sampled in 1997 (Povinec et al., 2003).

an option to generate electricity in 1948, when the X-10 Graphite Reactor was completed in Oak Ridge, Tennessee, the United States. A commercial NPP in Obninsk, Russia (formerly the Union of Soviet Socialist Republics (USSR)) began operation in 1954 to provide electricity from a nuclear source for the first time in human history. A total of 448 nuclear reactors were operating in 31 countries in 2016 according to International Atomic Energy Agency (IAEA, 2017). In addition, some 60 nuclear power reactors were under construction. The total net installed power in 2016 was 392,116 MWe according to IAEA. Nearly all the nuclear reactors are located near a large body of inland waters or the ocean, taking advantage of unlimited access to the heat sink of the reactor.

NPPs are mostly using uranium to produce electricity through the nuclear fission processes that produces thermal energy, which is then used to boil water and generate steam that in turn drives turbines connected to electromagnetic generators. Similar to the other thermal-electric generators, such as coal and oil burning power plants, less than 50% of the fission heat is converted to electricity, the extra heat needs to be disposed off in an ultimate heat sinks, such as a large body of water, e.g., rivers, lakes, and seas, or into the air. The sea is globally considered the most convenient ultimate heat sink to cool the condensate of the secondary cooling circuit in the coastal states. Therefore, large numbers of NPPs are located at the coast to take advantage of the sea as a heat sink. If not properly located or designed, those coastal reactors are subject to the risk of flooding, due to the increased frequency of severe weather or storm events and huge tsunamis caused by earthquakes that may cause accidents such as in FDNPP.

Contaminants emitted during the normal operation of nuclear power plants

Due to the scope of this encyclopedia, our discussion is largely confined to radioactivity. However, it should be noted that most industries and human activities serve the benefit of human civilization, and the unintended consequential damage to the human environment stems from those human activities that has been gradually curtailed over time largely thanks to both the scientific/technical engineering advances and adoption of innovative management practices. The biggest global pollution issue in our time is probably air pollution and human-caused climate change both due mostly to fossil fuel burning. Increase of greenhouse gas emissions, especially carbon dioxide, in recent decades is felt in the ocean in the form of acidification of the surface ocean where it contacts with the atmosphere (Hong and Povinec, 2021). The effects of nuclear power on human health (mortality) and the environment (climate) were recently quantified globally. Kharecha and Hansen (2013) used historical electricity production data and mortality and emission factors from the scientific literature to find that nuclear power prevented an average of over 1.8 million net deaths and an average of 64 Gt CO₂-equivalent net greenhouse gas emissions globally between 1971 and 2009. It is equivalent to

the past 35 years of CO₂ emissions from coal burning in the United States. Besides of CO₂, coal power plant emits particulate matter (PM₁₀ and PM_{2.5}), mercury, sulfur dioxide, nitrogen oxides, lead, carbon monoxide, volatile organics, arsenic, polonium and many other toxic chemicals to the air (e.g., Lin et al., 2019) as well as ²¹⁰Pb, ²¹⁰Po and other radionuclides, which may deliver locally higher radiation doses to the public than radionuclides released during normal operation of NPPs (e.g., Lauer et al., 2015; Mora et al., 2009).

Radioactive substances

Like other types of normally functioning industrial installations, including fossil fuel fired power plants, contaminants are released from NPPs during controlled nuclear fission operations. However, they are normally very small and do not represent a threat to humans and surrounding natural environment. Nonetheless, it should be acknowledged that NPPs do release some radioactive substances into air and sea. The United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR) reviews the sources and effects of ionizing radiation on a regular basis. UNSCEAR (2000) reported that radioactive noble gases, such as ¹³³Xe ($t_{1/2}$ = 5.3 days), and ¹³⁵Xe ($t_{1/2}$ = 9.2 h), ¹³¹I ($t_{1/2}$ = 8.02 days), tritium ($t_{1/2}$ = 12.3 years), ¹⁴C ($t_{1/2}$ = 5730 years), and other radionuclides are emitted to the atmosphere in small amounts. In addition, it is noted that the liquid effluents of the reactors during routine operation contain tritium, cobalt isotopes (⁵⁸Co, ⁶⁰Co), cesium isotopes (¹³⁴Cs, ¹³⁷Cs), ^{110m}Ag, ¹²⁴Sb, and other radionuclides (e.g., Kong et al., 2017).

Moreover, it is reported that many variations in types and quantities of radioactive materials emitted from different NPPs were detected, because of the great differences among the regulatory and operational measures of the different countries. The annual average effective dose to an individual due to the routine release of radiation from NPPs was estimated to be about 5 μ Sv/years, assuming that the total collective dose for each reactor type affects a single population group (UNSCEAR, 2000). Korean 24 NPPs were recently found to release about 0.4 PBq per year of total radioactivity into the environment in gaseous and liquid forms and their average effective dose to the members of public living near NPPs were estimated on the order of 1 μ Sv per year (Kong et al., 2017). This is orders of magnitude smaller than background radiation levels all human-beings are exposed to. For example, the total radioactivity of the naturally occurring gamma emitter ⁴⁰K in the global oceans of 15,000,000 PBq may be compared to that of 600 PBq, 16 PBq, and 15–18 PBq of ¹³⁷Cs from the atmospheric global nuclear weapons testing in 1950–1960s, Chernobyl in 1986, and Fukushima in 2011, respectively (Povinec et al., 2013a). ²³⁸U alone amounts to 37,000 PBq in the entire ocean (Buesseler, 2014). Therefore, the radiation impact from anthropogenic radionuclides in the world ocean on the human body is negligible because the maximum permissible annual limit for the public dose from exposure from external sources, including medical, educational, research and industrial facilities (IAEA, 2013) is usually set at most countries at 1 mSv/years, while the average natural global background dose is about 6.2 mSv/years (Health Physics Society, 2020). Fig. 4 shows the total quantities of radionuclides released from the East Asian NPPs.

Thermal effluent

Power plants powered by burning fossil fuel (coal and gas) or nuclear fission traditionally have required huge volumes of water to condense steam from the turbine exhaust (Pan et al., 2018). Generally, an NPP requires about 189 m³ of seawater cooling to produce 1 MWe (calculated using data provided by Korea Electric Power Corporation (<https://www.data.go.kr/data/15039187/fileData.do>), similar values are found in IAEA (2012)). Coal fired power plants require cooling water, but the volume required is slightly smaller (~10% less) because they usually have a higher thermal-to-electrical energy conversion efficiency. Advanced

Fig. 4 Total amount of radionuclides released annually from operating NPPs in China, Japan, Republic of Korea, and Taiwan. Data from UNSCEAR (2000) *United Nations Scientific Committee on the Effects of Atomic Radiation: Sources, Effects and Risks of Ionizing Radiation UNSCEAR 2000 Report*. NY: United Nations, 659 p.

NPP are expected to have energy conversion efficiency comparable to, or larger than the efficiency of coal-fired power plants (Pan et al., 2018; Stanculescu, 2021).

The volume of seawater required varies for each reactor, because the ambient seawater temperature differs in each NPP location. For example, the Yeong Kwang NPP, which houses six reactors, requires about 7.5×10^9 m³/years, which is equivalent to the amount of water in the third largest river in the Republic of Korea (Kum River, 6×10^9 m³/years) (Hong et al., 2002). The condenser cooling water, which carries the residual heat, is discharged into the sea at a temperature higher than the ambient water (6–11 °C higher in case of a low temperature condenser and 14–17 °C higher in case of a high temperature condenser) and it affects ocean temperature in the immediate locale. The amount of seawater circulated through condensers of all the NPPs operating in China, Japan, Korea, and Taiwan is about 567×10^9 m³/years, which is equivalent to that of the Mekong River (448×10^9 m³/years), about 2/3 of the Changing River (896×10^9 m³/years), and about 20 times of the discharge of the Han River, the largest river in the Republic of Korea.

Therefore, seawater circulation through condensers may thermally modify the marine ecosystems significantly in the vicinity of the points of seawater intake and discharge. These thermal effluents have been affecting the surrounding marine ecosystems (e.g., Huang et al., 2019), cold water species in particular, because they raise the water temperature by more than about 0.5 °C above the ambient water temperature in an area of about 12–30 km² surrounding the discharge pipe outlet (Maeng et al., 2013). In addition, the abrupt halt of discharge of thermal effluent due to routine plant shutdown causes cold shocks to the thermally elevated ecosystem near the outfall and forces it to readjust to the new settings. For example, NPP operators in the Republic of Korea have paid about 21 million US\$ annually for the last 5 years (2015–19) to the local fisheries interest groups in response to the alleged thermal damages on their cold species culture ground adjacent to NPP (Today Energy, 2019). This is partly due to the peculiar legal settings surrounding some kinds of territoriality fishing rights of local residents and other legitimate users of the sea in the Republic of Korea.

In a broader context, NPPs, fossil fuel powered power plants, and desalination plants have discharged thermal effluent into the sea, which significantly modifies temperature and salinity in the immediate receiving body of water (e.g., Kim and Jeong, 2013).

Other chemicals

Like other seawater intake pipes in other industries, including fossil fuel powered thermoelectric generators, the inner wall of the condenser of NPPs is subject to scale formation, colonization of marine organisms, and corrosion. These phenomena compromise the designed cooling efficiency. Therefore, they must be strictly controlled. Usually, scales, corrosion, and fouling are prevented using acidic polyphosphate and chromate solutions, amine or organosilicon compounds, and sodium hypochlorite, respectively. Foam forms in the downstream of the outlet of the condenser effluent because air is entrained at the weir, and cascades build up at the outlet structure and become persistent around the outlets. As a result of the growing public concern about the buoyant foam, various chemical de-foaming agents, such as polydimethylsiloxane (Stevens et al., 2001; Craig and Caunter, 1990; GESAMP, 1986) or other mechanical options have been used (Oh et al., 2012). The residues of these chemicals are discharged into the sea along with the thermal effluents. However, their impact on the marine ecosystem and humans is usually negligible.

Impact of the cooling water intake operation on the ecosystem

For both fossil fuel and nuclear thermoelectric generators, drawing a large volume of water at a high-speed leads to the simultaneous intake of large amounts of debris from the sea. Therefore, bar screens, double through traveling screens, drum screens, and debris filters are placed at the mouth of the intake. However, fish and other animals collide in the wire screen at the mouth of the intake tube and eventually die. The total amount of fish killed at NPPs along the coast of the Republic of Korea ranges from 3.4 to 30 t/years (Yi and Lee, 2016). Similarly, 258 t of fish kill were reported in the 2400 MW Longannet Power Station in January 1999 to December 2000 in the United Kingdom (Greenwood, 2008). In addition, small fish, eggs, and larvae of other marine organisms may pass through the filter screens and enter the cooling system, which threatens their mortality rates. Zooplanktons, such as euphausiid and scyphozoan medusa, often approach the screens in large volumes, which results in the clogging of the intake screens forcing NPPs to temporarily halt operations. The maximum tolerable densities of jelly fish and euphausiid were estimated to be about 2 and 800 individuals/m³ seawater, respectively (Lee et al., 2006).

Contamination of oceans due to nuclear reactor accidents

Waste products from nuclear reactors arise in two ways; (1) from the slow controlled reactions in nuclear power plant operations, including the production of reactor fuels and the burning of fuels in power reactors (1954–present) on land and sea going vessel (submarines, 1958 to the present); (2) from accidental releases to the environment from failed nuclear reactors (e.g., Chernobyl in 1986 and FDNPP in 2011), and (3) from the emission of technologically enhanced naturally occurring radioactive material (TENORM) from the non-nuclear industries (e.g., coal fired thermal powered plants, Pandit et al., 2011).

In the hydrogen explosions during the FDNPP accident, little dissipation occurred during this time due to the nature of the rapid global air circulation system. The Fukushima radioactive plume contaminated the entire Northern Hemisphere for a relatively short period of time (<21 days) when the westerlies circulated the earth with an average zonal velocity of >60 km/h, as shown in Fig. 5

Fig. 5 The centroid of the 8 days backward trajectory analysis at different sites around the world indicating the transport of the Fukushima plume and the centroid of the 19 days forward trajectories from Fukushima from 12 to 16 March. The number 1 is the identification number of the centroid and the percentage (100%) indicates the number of hourly trajectories occurring in the cluster. Hernandez-Ceballos MA, Hong GH, Lozano RL, et al. (2012) Tracking the complete revolution of surface westerlines over Northern Hemisphere using radionuclides emitted from Fukushima. *Science of the Total Environment* 438: 80–85.

(Hernandez-Ceballos et al., 2012; Povinec et al., 2013a,b). Earlier in 1986, ^{137}Cs emitted from the Chernobyl accident also affected its levels in the Sea of Japan (East Sea) in the opposite side of the globe almost immediately (Fig. 6).

The radionuclides discharged into the sea or falling on the surface of the ocean near the FDNPP have been subject to spread elsewhere in the Pacific Ocean by the aid of prevailing water currents, entering e.g. the Bering Sea and the Arctic Ocean (Povinec et al., 2013a,c; Huang et al., 2020; Tsumune et al., 2020). It is interesting to note that the declining trend of ^{137}Cs activity concentration in the Sea of Japan (East Sea) was reversed in the time period from 2011 to 2016 (Fig. 6). Hirose and Povinec (2019) confirmed the intrusion of Fukushima contaminated seawater through Korea/Tsushima Straits from the East China Sea using decoupling of ^{137}Cs and ^{90}Sr in seawater after 2011 (Fig. 7). The activity ratio of $^{90}\text{Sr}/^{137}\text{Cs}$ is extremely low (as much as 0.01–0.03) (Casacuberta et al., 2013; Povinec et al., 2013b), but the water originating off Fukushima of Japan carries the Fukushima $^{90}\text{Sr}/^{137}\text{Cs}$ signal. The Subtropical Mode Water off Fukushima flows westward as a form of undercurrent and entrained in the Tsushima Current to enter the Sea of Japan (East Sea) via shallow strait (~130 m deep). A part of ^{137}Cs introduced in the surface water is incorporated into the living and non-living suspended particulate matter and sinks to the bottom water. Owing to the relatively long residence time of the deep water (~1000 years), ^{137}Cs will accumulate in the deep water of the Sea of Japan (East Sea) similar to that of Pu isotopes (Hong et al., 2011).

Nuclear reactor failures and international governance

Accidents can happen in NPPs like they happen in any other large industrial installations. An “accident” can be defined as an event that happens unexpectedly and unintentionally, and typically results in damage or injury. However, the aftermath of an accident that involves a radioactive substance is potentially long-lasting, widespread, and can cause severe effects, such as destruction, damage, or injury to another state party. The Convention on the Prohibition of Military or Any Other Hostile Use of Environmental Modification Techniques 1976 (ENMOD) defines the following expressions: “widespread” refers to an area encompassing several hundreds of square kilometers, “long-lasting” refers to a period of a few months, and “severe” refers to the state involving serious or significant disruption or harm to human life, natural and economic resources, or other assets.

Radionuclides can exist in gaseous, liquid, or solid forms. In addition, they may spread into the air or water by prevalent wind and rain cycles. More importantly, they are invisible in most cases. Moreover, the radioactive decays of some radionuclides can take place over several, hundreds, or even millions of years and may extend much beyond the human lifetime. Therefore, they may modify the surrounding environment, regardless of their immediate adverse effects, and, thus, create additional concern because of the lack of scientific knowledge on their fate and behavior in the environment and natural ecosystems. Furthermore, the duration of exposure to radioactivity is more seriously considered by regulatory organizations—compared to that of non-radioactive

Fig. 6 Temporal variations in the ^{137}Cs activity concentrations in surface seawater in the Sea of Japan (East Sea) during the period from 1966 to 2016. Circles indicate measured values, and red circles indicate data measured after the Fukushima accident (March 11, 2011). Black circles indicate the 0.5-year average value. Standard deviations of data were removed to clearly show the temporal variation. Inomata Y, Aoyama M, Hamajima Y, and Yamada M (2018) Transport of FNPP1-derived radiocaesium from subtropical water in the western North Pacific Ocean to the Sea of Japan. *Ocean Science* 14: 813–826.

Fig. 7 Temporal variations of ^{90}Sr and ^{137}Cs in surface waters of the Sea of Japan (East Sea). Red dots show ^{90}Sr activity concentrations, and green dots show ^{137}Cs activity concentrations. The solid lines represent exponential regression curves. Hirose K, and Povinec PP (2019) ^{137}Cs and ^{90}Sr in surface waters of the Sea of Japan: Variations and the Fukushima Dai-ichi Nuclear Power Plant accident impact. *Marine Pollution Bulletin* 146: 645–652, with permission.

contaminants. The effluent standards of other contaminants, e.g. cadmium, is usually given in the form of concentration, although the health risk evaluation of these substances usually specifies the duration of exposure similar to that of the radioactive substances.

In 1956, 3 years after the first commercial nuclear reactor produced electricity, the cooling system of one of the waste storage tanks of the Mayak NPP and reprocessing facility, located in the Chelyabinsk region, failed, resulting in an explosion and contaminating a wide area (approximately 1000 km²). This accident was called the Kyshtym disaster and was ranked at level 6 on the

International Nuclear Events Scale (INES) (Thomas, 2012; Buttinger, 2017, 2017). In the year 1957, a fire broke out at the Windscale reprocessing plant in the United Kingdom with the emission of large quantities of ^3H , ^{131}I , ^{210}Po and other radionuclides into the air (e.g., Wakeford, 2007) and ^{137}Cs into the ocean along with other fission products (e.g., Livingston and Bowen, 1977; Povinec and Povinec, 2000).

In the same year (1957), the International Atomic Energy Agency was established. Since then, incidents and accidents involving nuclear material in nuclear power plants have occurred in more than 90 cases around the world (Rose and Sweeting, 2016). The nuclear reactor accidents that contaminated at least a half of the surface of the earth, including the ocean, were Chernobyl (Ukraine in 1986) and Fukushima (Japan in 2011). They occurred due to different causes, although human errors played a significant role in these accidents as well. However, a reactor of the Three Mile Island failed at level 5 on the INES in 1979 did not emit any noticeable amount of radioactive substance to the outside environment (Wheatley et al., 2017). In 1956 there was also a large-scale accident at the Windscale (UK) nuclear reprocessing facility.

Therefore, it is still difficult to generalize the cause of the accidents or the probability of nuclear reactor failures that discharge radioactive substances to the natural environment. But it is instructive to realize that the number of the major nuclear reactor accidents that contaminated marine environment is only two (Chernobyl and Fukushima) out of about 448 (0.45%) nuclear reactors in the world (see also Sich, 2021; and Mizokami and Rempe, 2021). That may be compared to that of the other accidents of manufacturing industries, for example, in S Korea (0.59% in 2012, Yi and Lee, 2016), though a different matrix was used. Also, in evaluating the total environmental impact of various power production sources, one must take into account the vast reduction in CO_2 pollution emissions provided by nuclear power in comparison to fossil fuel plants. Furthermore, it is important to note (i) the number of years the NPPs have operated or the total amount of energy they have generated should be factored in, and (ii) future advanced NPP are expected to be inherently safe, such that the probability that they will have accidents that contaminate the oceans will be much lower.

Unit 4 of the Chernobyl NPP was blown up at 01:23 on April 26, 1986 and caused the emission of a large amount of radioactive substances, which spread over the entire globe, especially in Northern Europe. However, Moscow did not announce the accident until April 28 at 21:02. The health, environmental, and socioeconomic impacts of the Chernobyl accident are still being assessed, and remedial measures are still being conducted in several countries. In addition, some affected areas in Ukraine are still abandoned (OECD, 2006; Beresford et al., 2016). The Chernobyl nuclear accident prompted various global countermeasures against nuclear accidents to clarify the duties of the accident states and create an international assistance mechanism.

The IAEA General Conference conducted the Convention on Early Notification of a Nuclear Accident and the Convention on Assistance in the Case of a Nuclear Accident or Radiological Emergency. Both were opened for signature on September 26, 1986 (5 months after the accident) and became effective on October 27, 1986 and February 16, 1987, respectively. Subsequently, Europe further developed collaboration mechanisms in a transboundary context, such as the Convention on Environmental Impact Assessment in a Transboundary Context 1991; the Convention on the Transboundary Effects of Industrial Accidents on March 17, 1992; the Convention on Access to Information, Public Participation in Decision-making and Access to Justice in Environmental Matters in 1998. Other activities were administered by the United Nations Economic Commission for Europe (UNECE) for industrial installations, e.g., NPPs and offshore oil and gas platforms that might have adverse environmental impacts across borders.

In 2011, the FDNPP accident (INES 7) occurred, resulting in the emission of a considerable amount of radioactive substances into the entire northern hemisphere. A magnitude 9.0 earthquake occurred at 14:46 on March 11, 2011 in the Pacific Ocean side of Northern Honshu, Japan, followed by a tsunami that struck the east coast of the Tohoku region. Three of the six BWRs operating at the FDNPP automatically shut down. However, a meltdown of the nuclear fuel reactor occurred shortly after the shutdown because the cooling system of the reactors failed due to the failure of the submerged diesel generators located in the flooded basement. Radionuclides were detected at the main gate of the plant at 12:00 on March 12, and a substantial number of radionuclides were released to the atmosphere after hydrogen accumulated within the reactor, resulting in the explosion of Unit 3 on March 14, 2011 at 11:00. The large magnitude of the atmospheric release continued until March 17 (Momoshima et al., 2012). In addition, about 24 days later, on April 4, nearly 10,000 m^3 of radioactive substances laden water was discharged to the Pacific Ocean. The Japanese government imposed a voluntary ban on fishing activities on March 15 (4 days after the nuclear disaster). Subsequently, China, Hong Kong, Taiwan, Singapore, the Russian Federation, the United States, and Australia have banned the imports of certain Japanese food items, including fishery products that originated in or near Fukushima.

The FDNPP accident revealed a number of important aspects of nuclear accidents in coastal areas:

- (i) Radioactive substances first released into the atmosphere had spread into the entire Northern Hemisphere within a few weeks (Hernandez-Ceballos et al., 2012; Povinec et al., 2013a) and had immediately arrived to the ocean surface (Buesseler et al., 2012; Povinec et al., 2013a,b).
- (ii) In the short period following the accident, all fisheries activities within a 20 km radius from the plant were suspended by the government.
- (iii) Seawater was used to cool the damaged reactors, which resulted in the discharge of water highly contaminated with radioactive materials into the sea.
- (iv) Sea bottom sediments adjacent to the plant were rapidly contaminated, which immediately led to the contamination of the overlying seawater.
- (v) Contaminated marine bottom sediments acted as a source of radioactive substances, to which the benthic fauna was exposed, i.e., longer retaining the radioactive substance in the bottom dwelling fish (Wang et al., 2018). Though none of the

- bottom-dwelling fish caught nearby exceed Japan's strict limit of radiocesium ($^{134}\text{Cs} + ^{137}\text{Cs}$) of 100 Bq kg^{-1} ww (wet weight) after 2015 (for surface-dwelling fish already after 2011), there has been public concern about the safety of the marine food.
- (vi) There were still more than 1000 massive water tanks on the premises containing waste water with many radiologically important radionuclides of relatively high concentrations (^3H , ^{14}C , ^{99}Tc , ^{125}Sb , ^{60}Co , ^{106}Ru , ^{137}Cs , ^{134}Cs , ^{90}Sr , ^{129}I) (Buessler, 2020), which were subjected to radio-purification, or eventually to be released into the sea (when containing only tritium). It is planned that about 1 Mt. of radioactive water containing tritium will be released to the sea for 30 years. A land-side impermeable wall (the so called "ice wall"), about 30 m deep and 1.5 km long, was constructed to prevent possible contamination of the groundwater. However, the stability of this wall has been recently questioned (Reuters, 2018).

The aftermath of the Fukushima accident was extraordinary, because all the details of the accident scene had been continuously broadcasted live from the start, and all the measures and the inter-governmental consultations were known to the general public before they were realized by the domestic and international authorities. The large uncertainties associated with the aftermath management, such as the amount and fate of the radioactive substances released from the accident beyond the country of origin (as well as the radioactivity records observed throughout the northern hemisphere) triggered many doubts and fear in ordinary people especially those living in neighboring countries. On the other hand, it should be stressed that there has not been reported any deaths which could be associated with radiation from the Fukushima accident.

During the last 25 years, the world has significantly changed, particularly after the Internet and World Wide Web became available to the public. Thereafter, the public gained access to an unprecedented amount of data and information previously owned by a few elite groups, such as state governments. The ocean and its resources are increasingly and simultaneously utilized by various international stakeholders. For example, the share of exports in fish production amounted to 37.6% in 2018 (FAO, 2020). Consequently, ordinary citizens who have access to up-to-date scientific data view marine space more like Transboundary Rivers. They regard it as shared transboundary waters similar to that of the Kiev Protocol on Civil Liability, the Compensation for Damage Caused by the Transboundary Effects of Industrial Accidents on Transboundary Waters, the 1992 Convention on the Protection and Use of Transboundary Watercourses and International Lakes, and the 1992 Convention on the Transboundary Effects of Industrial Accidents—all allowing individuals affected by the transboundary impact of industrial accidents on international watercourses (e.g., fishermen) to legally claim an adequate and prompt compensation. Pacific bluefin tuna flesh caught off California in August 2011, about 6 months after the March 2011 Fukushima accident, were found to have ^{134}Cs ($4.0 \pm 1.4 \text{ Bq kg}^{-1}$) and ^{137}Cs ($6.3 \pm 1.5 \text{ Bq kg}^{-1}$) above the pre-Fukushima accident ^{137}Cs ($\sim 1 \text{ Bq kg}^{-1}$) level (Madigan et al., 2012).

However, these increases are statistically insignificant increases above the global fallout background—which illustrates the misunderstanding of the public on radionuclide levels in the environment and specifically in food. The effective dose commitment estimated from consumption of such "radiocontaminated" tuna fish would be about $0.1 \mu\text{Sv/years}$, i.e. 10,000-times below the maximum permissible annual dose to the public from external sources (Povinec et al., 2013a; Povinec and Hirose, 2015).

The Japanese government imposed a strict limit of 100 Bq kg^{-1} ww (wet weight) on seafood (5-times lower than during the pre-Fukushima era, and 10-times lower than usually accepted international value). The total effective dose commitment estimated from the ingestion of ^{134}Cs and ^{137}Cs in fish, shellfish, and seaweed due to the FDNPP accident is 0.7 mSv/years (Povinec et al., 2013a). This value is still well below the maximum permissible annual dose to the public from external sources (1 mSv/years), and below the world average dose from natural radiation sources (2.4 mSv/years). The individual effective dose commitment from consumption of ^{134}Cs and ^{137}Cs in fish caught in the open north-western Pacific Ocean in 2012 was estimated to be about $2 \mu\text{Sv/years}$, i.e. 350-times lower than the dose from the consumption of natural ^{210}Po in fish and shellfish.

Ownership of the aftermath of marine environmental contamination in areas beyond the national jurisdiction

After the 2011 Great East Japan Earthquake, the media started to report real-time news of its development and its impact on the FDNPP accident and the subsequent release of radioactive substance into the air. Countries worldwide were notified of the radioactive substances released into the environment through the news media instead of the official diplomatic channels. Hence, they carried out extensive monitoring of the Fukushima originated nuclear substances according to their individual social needs, which were based on their individual economic and technological capabilities. Globally, the monitoring activities of the marine environment, such as sending ships to collect seawater, biota, and sediments—as well as carrying out subsequent laboratory analyses and a number of national and international meetings—had a significant cost. Therefore, recently mostly international cruises have been organized.

As a result of these efforts, radioactive substances originating from the Fukushima accident were found to have reached the west of Japan as well as passing the Pacific Ocean, America continent, Atlantic Ocean, Europe continent and going back to Japan (Povinec et al., 2013a). There have been several national and international sampling expeditions to collect samples of seawater and biota and subsequent analysis of key anthropogenic radionuclides in probably more than a few hundred laboratories around the globe. The sampling and further analyses are still being carried out and reported to the scientific communities and to the public. Handling and controlling the aftermath of the accident becomes an international concern, which may be regarded as a manifestation of the sense of the collective ownership of the aftermath, although each state carried out their monitoring activity for the protection of their state sovereignty. Therefore, there is good reason to establish a consultative committee of experts similar to that of the ENMOD to analyze the findings and provide expert views relevant to the problems encountered.

Precautionary principle versus risk-based approach

Contaminants in the environment are usually evaluated in terms of amounts, e.g., (i) a substance could be present in trace or negligible amounts; (ii) a tendency to be shortly converted to a harmless substance; (iii) safety factors; and (iv) safe or acceptable levels, which are often expressed in numeric figures. However, although these criteria appear to be scientific, they are almost impossible to be integrated in scientific methods, because uncertainty is a trait of science and scientific investigations. For example, the mean acute toxicity values (or LC_{50}) of marine organism species vary by five orders of magnitude, in which the highest concentration, for example of cadmium (135 mg Cd L^{-1}) is that of the oligochaete worm, and the lowest one ($41.3 \text{ } \mu\text{g Cd L}^{-1}$) is that of the mysid (Wang et al., 2010). Although these data do not permit the release of contaminants in concentrations higher than the LC_{50} value of a target species into the marine environment, some operators may use some of the higher limits as their operating criteria. These variations in values paralyze the decision on which value is the most suitable for the protection of the marine environment.

Body burden data is often established through toxicity testing, and then the relevant thresholds are decided based on the relation between them and their accompanying toxicity. Cd concentrations in the surface of relatively pristine seawater, which are commonly below 10 ng L^{-1} , are considered as a reference. In addition, the uncertainty increases if the health of organisms including humans is considered. Another example of the uncertainty is that of “black spot,” which is a necrotic shell disease of Crab (*Cancer pagurus*) that lives in British coastal waters. Many studies have investigated this disease, but they have generated very different explanations for its causes. For example, one scientific paper claimed that the cause of the disease is the high frequency of net injuries, while another paper in another area declared the cause to be aging, because of the low crab fishing activities in the area (Dethlefsen, 1986). Both of these arguments were used to advocate or reject sewage sludge dumping into the sea, respectively.

Therefore, in order to avoid the “paralysis of uncertainty” (McIntyre and Mosedale, 1997), the current environmental management practice is to adopt a no emission principle and waste prevention policy, i.e., the precautionary approach was chosen to be the administrative measure to avoid the inaccuracy of scientific predictions of the threats to the environment and human health and to seek less harmful alternative processes and available products (Santillo et al., 1998). Environmental regulations, such as wastewater discharge limits, continue to be based on numeric standards in various parts of the world, with the recognition that individual governments will adopt air, water, soil, or food quality standards to complement their individual end of pipeline discharge limit standards.

Unfortunately, the nuclear industry has yet to adopt the best practice to limit its impacts on the marine environment. The international law of nuclear energy originated as regulations for nuclear weapons, not as a part of environmental law for protection of the environment. Moreover, the International Atomic Energy Agency (IAEA) aims to promote atomic energy for peaceful use, and the protection of the environment is a byproduct of this effort. Therefore, it considers the subject primarily for an industrial activity rather than from an environmental point of view (e.g., article 2 of the IAEA Statute). In addition, the international community has been dealing with radioactive substances in a different manner, compared to the other substances. The Convention on the Prevention of Marine Pollution by Dumping of Wastes and Other Matter 1972 (LC) included radioactive wastes and other radioactive matter along with other contaminants, such as e.g. cadmium and cadmium compounds. However, it handed over the issues of the radioactive material to the IAEA because it is the competent authority to handle this subject among intergovernmental agencies (Sjoblom and Linsley, 1994; IAEA, 2015).

Before the LC in 1972, radioactive waste disposal at sea had been conducted by multiple countries ever since 1946 (IAEA, 1999) and the IAEA had already provided safety standards for the radioactive waste disposal into the sea in 1961 (IAEA, 1961). It gave numerical values for the concentration of the most hazardous radionuclides, e.g., ^{90}Sr in the surface layers of the sea (upper 1000 m) that should not exceed $10^{-9} \text{ } \mu\text{C/mL}$ ($37 \text{ Bq mL}^{-1} = 37 \text{ kBq L}^{-1}$ seawater). These earlier guidelines are no longer validated by the agency. Upon the request of contracting parties to the LC, IAEA submitted the provisional definition, and provided recommendations on dumping of radioactive wastes and other radioactive matters. It revised those definitions in 1978 and then again in 1986 (IMO, 1986). The value of high-level wastes has been lowered, and the condition of dumping sites has been modified to be more restrictive. Subsequently, the international consultancy requirement prior to the dumping was added in the 1986 version.

However, in 1994, the Contracting Parties to the LC suspended the use of the IAEA definitions, recommendations, and guidance, because of their decision to ban radioactive waste disposal at sea. In addition, the IAEA always stressed that, in the light of future technological developments and increased scientific knowledge, the guidance will continue to be revised when appropriate, which reflects the uncertain nature surrounding the use of numerical values as the sole decision criteria. For example, if the threshold of cadmium emission from a plant to the ambient air is 5 ppb, the operator may be immune from the prosecution by keeping the plant emission under 5 ppb. However, the plant operator should be held responsible for the harm caused to animals or plants living adjacent to the outfall as a result of the emission, even if the discharge standard is retained. This is a well-established legal norm in the domestic court, but it still has not been well founded in the general international law.

In summary, it is unfortunate that this continuing evolvement of often conflicting international approaches for prevention of potential ocean contamination remains cloudy. As such, the precautionary principle currently providing the overarching guidance suggests a goal of NO discharge of radioactive substances into the ocean. Whereas this sounds admirable, it may not be currently practical for all industries emitting contaminants into the sea. For example, municipal waste treatment plants discharge contaminants into the public waters according to the emission standards set by public authority, though some contaminants in treated wastewater remaining or not screened by the standards pollute the receiving water bodies (e.g., Rogowska et al., 2020; Freeman et al., 2020). It is fair to note that nuclear power plants operators, like any other industries, endeavor to evaluate feasible waste reduction and prevention techniques including process modifications to remove the hazardous constituents and on-site

closed-loop recycling. Common sense also recognizes the enormous degree of dilution provided by the incredibly vast amount of ocean water and naturally occurring radioisotopes are continuously getting into the oceans. Consequently, considerably more science and innovative engineering solutions (e.g., advanced fission reactors) needs to be included in future efforts to minimize/prevent pollution from all sources.

Application of the distribution of anthropogenic radionuclides present at sea for the environmental protection

Applications of anthropogenic radionuclides as tracers to investigate oceanic processes were extensively reviewed by Broecker and Peng (1982), Jenkins (2003), Povinec et al. (2011), and Hong et al. (2011). Since the ocean input history of anthropogenic radionuclides is relatively well known, many were utilized to trace their carrier phases in the sea as time markers. Several examples are listed here.

One of the most significant applications of anthropogenic radionuclides to climate studies up to the present is the utilization of the bomb tritium distribution in the North Atlantic. With its presence in intermediate and deep waters, it directly confirmed that the deep-water forms in the North Atlantic as was postulated by the box model of global ocean conveyor-belt circulation. The distribution of bomb-produced ^{14}C in the ocean has been instrumental in validating the global ocean carbon model, as well as providing a valuable tool to date marine samples for the recent past (~ 60 years) with high accuracy. ^{14}C has also been useful for tracing sources of organic matter in estuaries and the ocean.

^{54}Mn , ^{58}Co , ^{60}Co , ^{137}Cs can be used to study metal physiology, such as trophic transfer factors in biological organisms in the marine areas adjacent to the nuclear waste discharge facilities. ^{85}Kr , ^{90}Sr , ^{129}I , ^{137}Cs , ^{238}Pu , ^{239}Pu , ^{241}Am have great potential as tracers for ocean circulation, including deep water formation originated from regional climate changes (e.g., Pittauer et al., 2017). They likewise have the potential for tracing ice rafted sediment movements in the Polar seas (e.g., Landa et al., 1998).

Point-like sources of artificial radionuclides of ^{129}I and ^{236}U from nuclear reprocessing plants near La Hague and Sellafield were recently utilized to investigate spreading of the Atlantic Water pathways in the North Atlantic (Castrillejo et al., 2018, 2020). The arrival times and locations of radioactive fallouts over the globe from Mike and Bravo tests in the Pacific revealed vertical air structure over the Indo-Pacific Ocean (Machta et al., 1956). Similarly, the arrival times and locations of the Fukushima derived radionuclides at the North America, Europe and Asia were utilized to tracking the movement of westerlies in the Northern Hemisphere and its poleward shift in the current warming period (Hernandez-Ceballos et al., 2012).

Bomb radiocarbon assays have provided estimates of the age and growth of whale sharks—now shown to be living longer than 50 years. These sharks are the largest fish in the world and are highly valued in the eco-tourism industry (Ong et al., 2020). Given the rapid progress in marine environmental radioanalytical technology to enable small size samples and single atom counting, more scientific understanding utilizing temporal changes in the distribution of anthropogenic radionuclides in the ocean will be made in the subtle inner workings of the oceans (Povinec et al., 2020).

Although particle reactive short lived artificial radionuclides ^{134}Cs ($t_{1/2} = 2.06$ years) and ^{60}Co ($t_{1/2} = 5.27$ years) were introduced experimentally to trace fine sediment movement in a low energy environment such as pasture or to trace remobilization of recent overbank sediment on river floodplains during subsequent inundation events (e.g., Greenwood et al., 2014), fallout radionuclides of well-known input histories have been generally extensively used to trace the soil erosion in the terrestrial environment (e.g., FAO/IAEA, 2017) and subsequent transport and deposition in the aquatic environment such as lakes and coastal oceans (e.g., Froger et al., 2018; Fuller et al., 1999). Once the changes in provenance and accumulation rates of bulk sediment grains established over time since 1945 to the present using artificial or in combination with natural radionuclides, the concurrent particle bound contaminants or other matter input history have been reconstructed since the early 1970s (e.g., Hornberger et al., 1999; Kamula et al., 2017).

Conclusions

Global oceans have been contaminated due to large-scale atmospheric weapons testing from the 1940s to 1980s. Three large scale civilian nuclear industry installations (Windscale, Chernobyl, and Fukushima) have experienced serious accidents, triggered by various causes, resulting in the contamination of regional seas and oceans largely in the Northern Hemisphere in 1950s, 1980s, and 2010s, respectively. Radioactive contamination of oceans by human errors deteriorates the utility of the ocean in a near field coastal ocean area adjacent to the accident. However, the radionuclide contamination levels in a far-field coastal ocean areas have been insignificant with respect to human health. Considering that numerous NPPs are located at coastal areas and regional seas and that environmental protection treaties are not in place, there is an urgent need for developing a form of a legally binding agreement to ensure the safe operation of NPPs in a regional level (e.g., Convention for the protection of the Marine Environment of the North-East Atlantic (OSPAR Convention)) and to develop an international mechanism to deal with the radiological accidents in timely manner, even though the new GEN-IV of NPP are likely to be immune to operators' errors such as occurred in Chernobyl and FDNPP. On the other hand, the released radionuclides to the marine environment have been effectively used as tracers of marine and ocean-atmosphere processes for the protection of sustainable use of the oceans.

Despite the fact that the nuclear energy from primordial origin was largely responsible for the creation of planet Earth the way it came to be and for the evolution of life, the following warning from the 1957 publication (Revelle, 1957) may be still worth to repeat here. "As the use of atomic energy becomes more and more a part of our daily life it is essential that thoughtful attention in broad perspective be paid to the often subtle and perhaps profound effects of this new technology on man and his environment." The well-known input history of radioactive substances into the marine environment has been and will be extensively utilized to

deciphering ocean mixing and global circulation as well as to investigating sources, fates and transport of other chemicals and materials in the ocean environment, including estuaries and coastal environments.

Introduction

Radiation chemistry is a part of physical chemistry similar to photo-chemistry, plasma chemistry, ultrasonic-chemistry etc. Ionizing radiation produces abundant secondary electrons.

Following these primary events, the ions, secondary electrons and excited molecules undergo further transformations, exchanging charges and energy and reacting with surrounding molecules, thereby producing free radicals and other reactive species that finally evolve into new stable products. Therefore, radiation can modify physical, chemical and biological properties of materials.

Three main sources of radiation are applied for radiation processing. These are electron accelerators, gamma sources and X-ray units based on e/X conversion processes. Accelerators are capable of supplying electron beams in the energy range up to 10 MeV

*Retired

(Zimek and Chmielewski, 1993) and sources of the radionuclides Co-60 and Cs-137, which emit gamma rays of energy 1.17/1.33 and 0.662 MeV respectively (IAEA, 2005). The recent introduction of powerful new X-ray (Bremsstrahlung) radiation sources open new unexplored fields as well (Stichelbaut et al., 2004). Electron beams provide corpuscular radiation, characterized by limited penetration. The entire energy of high-energy electrons is deposited in relatively thin layers of material. In the case of X-rays and gamma rays, ionizing radiation is provided by photons that have no mass and are thus able to penetrate deeper into materials.

The cobalt-60 emitted gamma rays penetrate up to 300 mm of 1 g cm^{-3} density (in a material like water) on an equal intensity material entrance—exit basis. In contrast, the highest electron energy used in commercial applications, 10 MeV, penetrates only 38 mm. Dose rates of gamma and X-rays are 4–5 orders of magnitude lower as compared to electron beams. Therefore, throughput efficiencies of gamma and X-rays are significantly lower than those of e-beams. Electron beams are capable of delivering 100 kGy per second, whereas the typical dose rate for gamma rays is 2.8×10^{-3} kGy per second or ~ 10 kGy per h.

The radiation dose rate generated by an electron accelerator of 15 kW power is approximately equal to that generated by 1 MCi of the cobalt source. When an Electron beam passes through matter (or a metal target on its way), it slows down and a fraction of its energy is directly converted into X-rays. This phenomenon is called *Bremsstrahlung* (German word) from *bremsen* “to brake” and *Strahlung* “radiation”; i.e., “braking radiation.” The X-ray target conversion efficiency is defined to be the fraction of EB energy converted into X-rays. The actual fraction varies with the atomic number of the metal used, but it is typically no higher than 5–8%. In practice this means that in order for an X-ray to process products with the same speed as a 10 MeV, 50 kW e-beam, it will need to have 625 kW of power. Over the last few decades, extensive work has been carried out for utilizing radiation technology for environmental remediation like flue gases from the power industry based on fossil fuel combustion purification, industrial wastewater treatment and municipal wastewater sludge hygienization, hospital waste sanitization, etc. (Chmielewski, 2005; Chmielewski and Han, 2016).

Flue gas treatment

Fossil fuels, which include coal, natural gas, petroleum, shale oil and bitumen, are the primary global sources of heat and electrical energy production. They are responsible for emitting a large number of pollutants into the atmosphere with off-gases from industrial use, power stations, residential heating systems, and vehicles. All these fuels contain major constituents (carbon, hydrogen, oxygen) as well as other trace materials, such as metals, sulfur and nitrogen compounds. During the combustion process, different pollutants like fly ash, sulfur oxides (SO_2 and SO_3), nitrogen oxides ($\text{NO}_x = \text{NO}_2 + \text{NO}$) and volatile organic compounds are emitted. Wet and dry deposition of inorganic pollutants leads to acidification of the environment. These phenomena affect human health, increase corrosion, and destroy forests and agricultural crops.

Wet flue gas desulfurization (FGD) and selective catalytic reduction (SCR) can be applied for flue gas treatment and SO_2 and NO_x emission control. All these technologies are complex chemical processes; and waste, like wastewater, gypsum and used catalyst, are generated.

Electron beam flue gas treatment technology (EBFGT) is a dry-scrubbing process of simultaneous SO_2 and NO_x removal, where no waste except the usable by-products are generated. Studies show that irradiation of flue gases with an electron beam can bring about chemical changes that make removal of sulfur and nitrogen oxides easier. The main components of flue gases are N_2 , O_2 , H_2O , and CO_2 , with much lower concentrations of SO_x and NO_x . NH_3 is used as an additive to aid the removal of the sulfur and nitrogen oxides. Radiation energy is absorbed by gas components in proportion to their mass fraction in the mixture. The fast electrons slow down and secondary electrons are formed, which play an important role in overall energy transfer. After irradiation, fast electrons interact with gas, creating various ions and radicals. In the case of high-water vapor content in the treated off gases, the oxidizing free radicals concentration is high. These species take part in a variety of ion-molecule reactions, neutralization reactions, and dimerization. After humidification and lowering of the temperature, flue gases are guided to a reaction chamber, where irradiation by an electron beam takes place. Ammonia is injected upstream from the irradiation chamber. Nitrogen oxide is reduced to atmospheric nitrogen. The byproduct formed in the process is a mixture of ammonium sulfate and nitrate, which is a good fertilizer component.

Electron beam flue gas treatment industrial plants have been constructed in coal-fired plants in China and Poland (Fig. 1) (Chmielewski, 2011). The installation consists of four main separated systems: flue gas conditioning unit, ammonia storage and injection unit, process vessels, and by-product collecting and storage unit (Fig. 2).

The first industrial installation for the simultaneous removal of SO_2 and NO_x was located in the Electropower Station “Pomorzany” in Szczecin (Fig. 1), in the north of Poland. The installation purified flue gases from two Benson co-generation boilers, which provided 65 MW of electricity and 200 MW of thermal energy to help heat the town. The total maximum flue gases flow rate is $270,000 \text{ Nm}^3/\text{h}^1$ (Chmielewski, 2019).

Recently, there has been significant concern about the air pollution from marine sources that currently utilize low quality diesel fuels. As a result, research and development projects have focused heavily on creating a cost-effective technology that can clean off gases with a high level of efficiency.

Exhausts from marine engines contain nitrogen, oxygen, carbon dioxide and water vapor as well as nitrogen oxides, sulfur oxides, carbon monoxide, various hydrocarbons and complex particulate matter. The maritime transporters usually use heavy fuel oil (HFO) with a high content of sulfur, which naturally leads to the three main pollutants derived from shipping: nitrogen oxides (NO_x), sulfur oxides (SO_x) and particulate matter (PM). Around 15% of global NO_x and 5–8% of SO_x emissions are attributable to ocean-going ships. SO_2 emission as a smog component is a precursor to acid rain and it can have a negative influence on plant life as well as on wider ecosystems.

Fig. 1 View of EPS Pomorzany, Szczecin, Poland. Flue gas humidifier tower of EBFGT plant—front left.

Fig. 2 Scheme of installation for radiation treatment of coal fired boiler flue gases.

A new, hybrid technology is based on the concept of combining two methods used to clean up the exhaust gases: Electron Beam (EB) and Wet Scrubbing. A new emerging hybrid technology that couples the Electron Beam with the reduced size wet scrubbing methods may provide an answer to reducing emissions from the marine shipping industry (King et al., 2019). There are two main stages involved: (1) SO_2 and NO_x (mainly nonsoluble and nonreactive NO) oxidation during irradiation by the Electron Beam from the accelerator and (2) the transformed by irradiation well soluble pollution products (SO_3 and NO_2) absorption into aqueous solution. The technology has been developed by INCT and tested in Warsaw, Poland in laboratory scale (King et al., 2019) and in pilot plant scale with application of mobile accelerator system developed by Fraunhofer FEP of Dresden (Germany) (CERN, 2019).

Wastewater treatment

Increasing urbanization in the last two centuries has been accompanied by an expansion of sewage collection systems without any or adequate treatment. Liquid waste loads have become so large that the self-purification capacity of receiving streams down-stream of large populations can no longer prevent adverse effects on water quality. These wastes now constitute significant sources of water pollution. The industrial effluents carry chemical contaminations such as heavy metals, organic pollutants, petrochemicals, pesticides and dyes, while the discharge of sewage and sludge gives rise to microbiological and chemical contamination of water bodies. The discharge of such materials into water bodies is responsible for risk of infection, health effects caused by contaminated drinking water and offensive odors. Therefore, all these industrial and municipal wastewater systems need adequate treatment.

Radiation processing of wastewater treatment is non-chemical, and uses fast formation of short-lived reactive species that can interact with a wide range of pollutants. High-energy irradiation produces instantaneous radiolytic transformations by energy transfer from high energy photons or accelerated electrons to orbital electrons of water molecules. Absorbed energy disturbs the electron system of the molecule and results in breakage of interatomic bonds. These become the most important products of the fragmentation and primary interactions (radiolytic products). High chemical reactivity is characteristic of water radiolysis products. A typical time for their reactions with the impurities in water is, as a rule, less than 1 μ s.

A large number of substances such as hard surfactants, lignins, and pesticides cannot be degraded by conventional biochemical methods. Thus, they escape from decomposition in biological treatment. Biodegradation quality of wastewater depends on the oxidation level and structure of pollutants. Preliminary oxidation and fragmentation of biologically resistant molecules contribute to the improvement of their biodegradability.

The above-mentioned mechanism of radiolytical oxidation provides the possibility for the required transformation of various pollutants (Sampa et al., 2007). Research and industrial treatments testify significant improvements of pollutant biodegradability after radiation-oxidation in aerated wastewater. Usually a dose of about 1–2 kGy is necessary for complete transformation of biologically resistant pollutants to a biodegradable state. EB TECH Co, DYETEC, and KAERI built an installation of a high-power accelerator (1 MeV 400 kW) and wastewater treatment system in the Daegu Dyeing Industrial Complex (DDIC), Korea, and started operation of the plant. This plant treats up to 10,000 m³ of textile dyeing wastewater (from the total of 80,000 m³) per day and has shown good removal of non-degradable organic impurities (Han et al., 2012). This is a breakthrough in the technology implementation, worldwide, and the biggest wastewater treatment plant ever built based on an electron accelerator unit (Fig. 3).

Other possible an accelerator application is ballast water treatment. The discharge of sea water used for ballasting ships poses a threat to coastal ecosystems. The introduction of alien species from ballast water discharge may lead to excessive development of these organisms in the new environment and cause a threat to native plant and animal communities. Low salinity is the basic natural factor shaping the biodiversity of the Baltic Sea and results in a small species diversity in comparison with other seas. Therefore, brackish seas, such as the Baltic Sea, are particularly sensitive to newly introduced species because they are poor in native species. In 2004, the International Maritime Organization (IMO) developed the Convention on the Control and Management of Ship's Ballast Water (BWM Convention), which provides a uniform legal regulation of the ballast water problem around the world.

In accordance with the legal requirements, ships, including docks, may only discharge ballast water if the number of microorganisms in the discharged water does not exceed:

- for *Vibrio cholerae* (contagious less than 1 colony forming unit (cfu) per 100 mL or less than 1 cfu per 1 g (wet weight) of zooplankton samples,
- *Escherichia coli* less than 250 cfu per 100 mL,
- *Enterococci* (intestinal) less than 100 cfu per 100 mL.

A ship, before entering a shipyard, has to replace the ballast water (with its antibiological treatment) in open waters. However, some waters still remain, together with solid state sediments containing biological contamination. When the ship is placed on the dry

Fig. 3 Industrial EB plant (10,000 m³/day) for textile dyeing wastewater in Daegu, Korea.

dock for maintenance (repair, painting, etc.), this ballast water has to be discharged. For the controlled pathogens, the D_{10} dose [kGy] resulting in a 10-fold reduction in the population is as follows:

- *Vibrio cholerae*, *V. parahaemolyticus*, *V. vulnificus*, $D_{10} = 0.1$ kGy,
- *E. coli* $D_{10} = 0.5$ kGy,
- *Enterococci* $D_{10} = 0.6$ kGy.

To enhance a better implementation of technology from the laboratory scale to commercial scale, the continuous operation by pilot scale is essential. For this purpose, a mobile e-beam plant has been designed in several countries. This movable plant (Han et al., 2016) is for individual field applications with a self-shielded structure that fulfills necessary safety requirements (Fig. 4). It can be used for on-site test of waste up to 500m³ of liquid waste per day at 2 kGy or 2000 Nm³ of gases from oil fired boiler in Jeddah, Saudi Arabia at 15 kGy per h (Pawelec et al., 2016).

Sludge hygienization and biohazards

In addition to treating wastewater, research has shown that sewage sludge can be disinfected successfully by exposure to high-energy radiation. At a plant near Munich, doses of 2–3 kGy have destroyed more than 99.9% of the bacteria present in sewage sludge, and at a plant near Boston a slightly higher dose (4 kGy) was used. Higher doses (up to 10 kGy) were required to inactivate more radiation resistant organisms at plants in Albuquerque. Both gamma sources (Co-60, Cs-137) and electron accelerators can be used for the irradiation of sewage sludge (Chmielewski et al., 1995; Kim et al. 2005). Two industrial gamma irradiation plants are working in India and several pilot plants using both type of irradiators were tested all over the world. Gamma source plants were operated in Albuquerque USA and Geiselbullach, Germany along with electron beam-based plants at Deer Island, Boston (Lessel and Suess, 1984; Hossain et al., 2018).

Gamma sources have better penetration, allowing thicker layers of sludge to be irradiated, although they are less powerful and take a longer irradiation time than electron beam sources. A pilot plant using a gamma source is operating in India (Sabharwal et al., 2005). The irradiator system (Fig. 5) can be easily integrated with a conventional treatment plant with flexibility of operation (Fig. 6). Lower radiation dose treatments can be imparted to the sludge with an addition of sensitizing agents such as oxygen, air, ozone etc. About 3 kGy of absorbed dose in sewage sludge removes 99.99% of pathogenic bacteria consistently and reliably in a simple (from technical point of view) process.

The use of radiation treatments allows for the complete elimination of nematodes and parasitic eggs (*Ascaris* sp., *Trichuris* sp., *Toxocara* sp., ATT) and the practical elimination of pathogens, such as contagious bacterial contamination and *Coliform*

Fig. 4 Mobile e-beam plant on EBFGD in Saudi Arabia (upper) and Wastewater treatment in Brazil (bottom).

Fig. 5 Photo of the gamma irradiator in Baroda, India (left) and its scheme (right).

Fig. 6 Scheme of the installation—gamma irradiator treating excess biological sludge from conventional wastewater treatment plant.

titer (decreased by three orders of magnitude for dose 1 kGy), *Clostridium perfringens* titer (decreased by five orders of magnitude for a dose of 1 kGy). The irradiated sludge being pathogen free can then be beneficially used as manure in the agricultural fields as it is rich in nutrients required for the soil. Since the irradiated sludge is free from bacteria, this can also be used as a medium for growing useful bacteria like *rhizobium* and *azetobactor* to produce biofertilizers, which can be used to enhance the crop yields.

A new concept “zero energy” biogas plant is based on the construction of a complex system consisting of a biogas plant and an electron accelerator in the biofertilizer manufacturing line. Digested material (in which organic solids were decomposed into stable substances) originating from the methane fermentation of sewage sludge is irradiated to remove all pathogens using an electron beam from an accelerator powered by electric energy obtained from burning biogas in a co-generator. The product is a high-quality, biologically safe fertilizer (Chmielewski and Sudlitz, 2019).

Special applications have evolved regarding biohazards combat. For example, *Anthrax* that was sent in the US mail in October 2001 caused several deaths and large economical losses. Radiation proved to be very effective for mail decontamination. About 4000 tons of letter mail and 200 tons of parcels had been sanitized by the end of 2003 (Desrosiers, 2004). The mail is being irradiated at a Titan Facility in Lima, Ohio and an IBA facility in Bridgeport, New Jersey. Both of these facilities are operating as electron beam irradiation units (EPA, 2019).

Acknowledgments

The work reported by AGCh has been financed by EU ARIES project (EU grant agreement 730871) and related to it MS&HE grant 3697/H2020/2017/2.e. The EB sludge hygienization work is financed by IAEA CRP (F23033) and MS&HE co-financing project, and POIR.04.01.04-00-0078/17, and EB ballast water treatment by Sector Program INNOship Project POIR.01.02.00-00-0007/18” granted by National Center for Research and Development, Poland.

Glossary

HEU Highly enriched uranium—uranium containing 20% or greater of the isotope U-235.

MORC Material out of regulatory control—nuclear or radioactive material that should be under regulatory control that is not currently, either from failure of the controls or because it was never under control.

NORM Naturally occurring radioactive material—radioactive material composed of only of materials that occur in nature.

PRD Personal radiation detector—small handheld gamma radiation detectors typically used to provide an early indication of radiation above background.

RDD Radiological dispersive device—illicit device designed to scatter radiation over a general area, for example a dirty bomb that combines an explosive with radioactive material.

RID Radioisotope identification device—radiation detector capable of identifying specific radioisotopes using gamma spectroscopy.

RPM Radiation portal monitor—passive radiation detectors used for screening pedestrians, vehicles, and cargo for the detection of illicit movement of gamma and neutron radioactivity, typically deployed at points of entry.

SPM Spectroscopic portal monitor—a radiation portal monitor that is able to identify specific radioisotopes using gamma spectroscopy.

Weapons-grade plutonium Plutonium greater than 90% in the isotope Pu-239.

Introduction

The movement of radioactive materials across international borders is vital to modern society for medicine, science, and commerce. However, when these valuable materials are no longer within regulatory control, either through accidental loss, inadvertent transport, or illicit activities, they represent a global concern requiring national and sometimes international cooperation. The loss of control of radiological and nuclear materials has the potential to effect human health, damage economies, degrade the environment, and impact society. The potential threats for using radioactive materials for terrorist acts include acquisition of a nuclear explosive device, nuclear material to build an improvised nuclear device, material to construct a radiological dispersive or exposure device (RDD), or the potential attack/sabotage of a facility using radioactive material.

The three major pillars of international nuclear security are prevention, detection, and response. Preventing the loss of regulatory control over nuclear and other radioactive material is the initial layer of defense and the strategy with the highest probability for success. Prevention is often summarized as “guns, gates, and guards,” but it involves more than just physical protection. Prevention includes material balance accounting, regulatory licensing and oversight, and establishing laws and regulations criminalizing the theft or diversion of materials. When material falls out of regulatory control, detection systems and measures focus on locating the material through information alerts and/or instrument alarms. Response is the third layer of defense where resources are used to control and mitigate circumstances resulting from a nuclear security incident, with the goal of controlling and stabilizing the situation and returning the material to regulatory control. This article focuses on international efforts to support border security and detection of radioactive material out of regulatory control (MORC) at traditional border crossing points.

Initial efforts for increasing border security for the detection of radioactive MORC were driven by incidents of orphan radioactive sources in shipments of scrap metals that resulted in radiation exposure to the public such as apartments built with cobalt-60 contaminated rebar (Chang et al., 1997) and contaminated materials from the Chernobyl accident. International efforts to improve border security for detecting radiological and nuclear materials increased dramatically following the breakup of the former Soviet Union and the September 2001 terrorist attacks on the United States.

Responsible organizations

Nuclear and radiological security, including nuclear security measures as they apply to border security, is a responsibility of individual countries; however, there is also tremendous international cooperation in this area. Major international organizations participating in nuclear security detection at borders include the International Atomic Energy Agency (IAEA), World Customs Organization, European Commission’s Directorate General for Taxation and Customs, International Criminal Police Organization (INTERPOL), European Union Agency for Law Enforcement Cooperation, United Nations Office of Drugs and Crime, United Nations Interregional Crime and Justice Institute, and the Global Initiative to Combat Nuclear Terrorism (GICNT). In addition, there are many countries that are involved in bilateral and multilateral cooperation. Rather than dealing with individual country efforts, this article summarizes joint efforts for international agencies that assist countries in developing capacity and sustaining a nuclear security regime and detection architecture. The Nuclear Security Summit series of international meetings held in Washington D.C., USA in 2010; Seoul, South Korea in 2012; the Hague, Netherlands in 2014; and Washington, DC, United States in 2016 provided a showcase of international efforts to improve the security of radiological and nuclear materials. In addition, there are informal mechanisms for international cooperation such as the Border Monitoring Working Group (BMWG).

The IAEA Nuclear Security Series documents are recommendations for IAEA Member States to establish and sustain systems and measures for nuclear security, and more broadly a national-level nuclear security detection architecture. These documents are organized into four categories: fundamentals, recommendations, implementation guides, and technical guidance. Fundamentals are the highest-level document and provide overarching objectives and principles, the basis for recommendation documents, and references to international agreements. Recommendations are the application of the fundamentals and provide general approaches, applications, concepts, and strategies. Implementing guides provide the ways and means on how the recommendations are to be applied. Technical guidance documents provide the details on implementing and operating nuclear security systems and measures, and can include reference manuals, training guides, and service manuals. The IAEA also produces non-consensus-based technical documents that can include training guides and service manuals.

The IAEA Incident and Trafficking Database (ITDB) was established in 1995 and provides a valuable resource for reviewing incidents of nuclear and other radioactive MORC. Reporting to the ITDB is voluntary with 136 Member States participating at the end of 2017. The database covers incidents and trafficking of nuclear material, naturally occurring radioactive material (NORM), radioactively contaminated material, and commercial radioactive material. In addition, reporting of incidents of fraud (e.g., scams or hoaxes) claiming nuclear or radioactive material is also encouraged. The ITDB is confidential for Member States and the IAEA; fortunately, the IAEA provides a public domain summary of the reported incidents through an annual fact sheet. The 2018 fact sheet shows a total of 3235 confirmed incidents have been reported from 1993 to 2017. Of these incidents, 278 are confirmed or likely cases that involved trafficking or malicious use. Of the confirmed trafficking or malicious use cases, 12 involved highly enriched uranium (HEU), two involved plutonium, and four involved plutonium/beryllium neutron sources. An additional 913 incidents were recorded without enough information to determine whether trafficking or malicious use took place. All other cases were determined to not, or likely to not, relate to trafficking or malicious use.

The World Customs Organization is an independent intergovernmental body whose Member States work to enhance the effectiveness of custom services relative to regulated trade, and public and environmental safety. Customs organizations have a unique role in border security through the ability to interdict MORC at national borders, either prior to entering or exiting a country's boundaries.

INTERPOL assists in border security for the detection of nuclear and radiological material through information sharing, capacity building, and support for operations, investigations, and prosecutions. INTERPOL supports border security by issuing cooperation notices at the request of each partner country's National Central Bureau. INTERPOL's color-coded notices are international requests for cooperation or alerts, ranging from wanted persons, missing persons, additional information, unidentified bodies, warnings and intelligence, imminent threats, modus operandi of criminals, and joint INTERPOL–UN Security Council special notices. INTERPOL maintains the Geiger database that compiles law enforcement information on potential illicit activity concerning radiological material. INTERPOL member countries can use the Geiger database for conducting risk/threat and trend analyses. Access to both the IAEA ITDB technical data and Geiger criminal data provides a tremendous resource for partner countries in investigating or prosecuting criminal activity and can assist with designing a nuclear detection architecture. INTERPOL also assists in building capacity for border security by facilitating training and workshops.

The BMWG was established in 2005 by the IAEA, European Union, and United States to promote cooperation between its Members and serve as a forum for discussion and exchange of information on plans and programs to be implemented by the Members in cooperation with recipient countries to combat the illicit trafficking of nuclear and other radioactive material (Abousahl et al., 2014). Specific areas of cooperation include radiation detection equipment deployment, training, and long-term sustainability. The BMWG provides an effective tool for avoiding duplication and maximizing resources. For example, joint assessment missions are conducted to ensure common approaches and practices for the assistance and support provided. Group members also implement joint projects to coordinate the deployment and sustainment of equipment through organizing joint workshops and exercises and providing joint training. In the field of training, representatives of the three organizations have worked on development of curricula for frontline officers on radiation detection techniques and for the development of officers as trainers. The BMWG cooperates on research and development aspects related to radiation detection technologies and is involved in the testing of the equipment. The group also encourages and supports targeted projects in areas where the scientific and technical work can bring measurable added value to end users, such as reducing the number of NORM alarms from scintillating plastic radiation portal monitor (RPM) detectors.

The GICNT is an international partnership of 88 nations and six international organizations that are committed to strengthening global capacity to prevent, detect, and respond to nuclear terrorism. The GICNT works toward this goal by conducting multilateral activities that strengthen the plans, policies, procedures, and interoperability of partner nations. All partner nations have committed to implementing the GICNT Statement of Principles, a set of broad nuclear security goals encompassing a range of deterrence, prevention, detection, and response objectives. The eight principles contained within the statement aim to develop partnership capacity to combat nuclear terrorism consistent with national legal authorities and obligations as well as relevant international legal frameworks such as the Convention for the Suppression of Acts of Nuclear Terrorism, the Convention on the Physical Protection of Nuclear Material, and United Nations Security Council Resolutions 1373 and 1540. The United States and Russia serve as co-chairs, while Morocco leads the Implementation and Assessment Group under guidance of the co-chairs. The GICNT conducts multilateral activities and senior-level plenary meetings, and is open to nations that share in its common goals and are committed to combating nuclear terrorism. The GICNT has a Nuclear Detection Working Group chaired by the United Kingdom, a Nuclear Forensics Working Group chaired by Canada, and a Response and Mitigation Working Group chaired by Argentina.

Radioisotopes of concern for border security

Major radioisotopes of concern for border security can be grouped into four major categories: nuclear material, radiological materials, NORM, and medical. The most significant radioactive threat materials are nuclear weapons or components, HEU, weapons-grade plutonium, and commercial radioisotopes with high activity and half-lives with reasonable persistence (e.g., cesium-137 and cobalt-60 irradiators and sterilization sources, iridium-192 radiography) that could be used for radiological disperse or exposure devices. Most of these isotopes of concern emit penetrating ionizing radiation with either a gamma or a gamma/neutron signature. Instrument-based detection equipment at border security locations can detect gamma and neutron radiation. Alpha and beta radioactivity is non-penetrating and is easily shielded by packaging, luggage, and vehicle panels and is therefore not useful for initial screening by radiation detectors at border crossing points. However, many of the alpha and beta emitting radioisotopes also emit gamma radiation and, in the case of beta radiation, there may be some detectable Bremsstrahlung X-ray radiation produced from interaction of the beta radiation with container walls.

Nuclear materials are fissile isotopes that can be used in commercial nuclear power reactors, naval vessels, and for nuclear weapons. The materials of most concern are HEU and weapons-grade plutonium. Although there are other materials that are technically nuclear, they are not practical or available in sufficient amounts for use in weapons (e.g., americium-241). HEU is defined as uranium containing 20% or more of the isotope uranium-235 (IAEA, 2001). HEU emits low-energy gamma radiation, no readily detectable neutrons, and is relatively easy to shield. Plutonium is primarily an alpha emitter, but it also emits both gamma and neutron radiation; neutron radiation is difficult to shield. A neutron-only alarm can be suspicious because it is likely that someone has tried to shield the material and may be an indication of plutonium.

NORM contains long-lived radioisotopes that are ubiquitous in our environment and can be found in many products, construction materials, and geological formations (e.g., truckloads of granite or fire bricks). NORM is the most frequent cause of gamma radiation alarms in customs and border security applications (Kouzes et al., 2002). In large quantities NORM can trigger a gamma alarm. The most commonly encountered NORM radioisotopes are potassium-40, uranium, and thorium and their associated decay products (e.g., radon daughters) (Eisenbud, 1987). Recently the IAEA has released a mobile application (the Tool for Radiation Alarm and Commodity Evaluation or TRACE) to assist frontline officers in determining if radiation alarms generated from cargo shipments are potentially from NORM or an illicit shipment.

Certain radioactive isotopes are used in a wide variety of industrial and medical applications and are commonly encountered in commercial shipping. For example, cesium-137 is used to measure flow in pipelines and as a transmission source in radiography devices, and cobalt-60 can be used to sterilize surgical instruments and in medical therapy. However, these isotopes are also likely source materials for making radiological dispersive devices (RDDs or dirty bombs) or radiological exposure devices. The properties suitable for constructing an RDD include availability in commercial or medical devices, high activity, and moderate to long radioactive half-life. This leads to a relatively short list of radioisotopes of concern that includes: americium-241, californium-252, cesium-137, cobalt-60, iridium-192, plutonium-238, polonium-210, radium-226, and strontium-90.

Medical pharmaceuticals (e.g., technetium-99m and iodine-131) are widely used throughout the world for diagnosis and treatment of disease. While these medical sources can have moderate to high activity, they generally have relatively short half-lives and are not considered a major threat for illicit activity in RDDs. Due to the short half-lives of most radiopharmaceuticals, frontline officers typically encounter these isotopes when monitoring airports and express shipping containers. Frontline officers more frequently encounter radiopharmaceuticals when patients under active treatment are detected by instruments at border crossing points. Some patients can have enough activity to set off radiation detection equipment in multiple vehicle monitoring lanes (Kouzes et al., 2002). Radiation alarms at border crossing points can be cleared through a medical document check and/or using a handheld radioisotope identification detector (RID).

Preventing the loss of regulatory control of radioactive materials is of paramount importance for nuclear security (IAEA, 2002a). Placing radioactive sources under strict physical security, eliminating the use of radioactive sources by applying alternative technologies, and applying regulatory oversight can reduce the chance of a source falling out of regulatory control. Once a source falls out of regulatory control, we must rely on the more limited detection and response pillars to resolve to the situation.

Detection

There are two approaches for detection of MORC: information alert and instrument alarms (IAEA, 2002b).

Detection by information alert

Information alerts can come from a wide range of sources but most are reports of regulatory noncompliance or loss of regulatory control, suspicious activity, public reporting, medical observations (e.g., emergency room indications of radiation exposure), international databases (e.g., IAEA and INTERPOL), bilateral or multilateral information and data sharing, and country-specific operational information such as informants and traditional intelligence. The observation and investigative skills of frontline officers have resulted in many seizures of radioactive MORC. The seizure of HEU without the aid of radiation detection equipment by an attentive and proactive frontline officer at the Bulgarian border is an excellent example (Niemeyer and Hutcheon, 2003; Keegan et al., 2016). A review of proliferation incidents involving fissile material trafficking reported that traditional investigative methods such as observations during unrelated investigations, undercover sting operations, reports of missing inventory material to security forces, anonymous tips, and observational skills during routine operations resulted in most of the incidents (Potter and Sokova, 2002). Detection by information alert is particularly valuable in cases where traffickers attempt to use masking or shielding to limit the ability of detection equipment.

Detection by instrument alarm

Alarms are generated when thresholds for detection equipment are exceeded, typically at an inspection point that is situated at a border crossing or other port of entry (e.g., airport, ferry terminal). Typical equipment at inspection points includes RPMs, personal radiation detectors (PRDs), handheld radiation detection and/or isotope identification equipment, metal detectors, and X-ray systems. RPMs are in wide use worldwide for border crossings or ports of entry. For example, the U.S. Department of Energy's National Nuclear Security Administration has partnered with more than 70 countries to jointly deploy nearly 800 radiation detection systems, primarily RPMs. RPMs are used to screen pedestrian, vehicle, truck traffic, and cargo containers for penetrating radiation (gamma and neutron). The IAEA Nuclear Security Series *Technical Guidance on Technical and Functional Specifications for Border Monitoring Equipment* (IAEA, 2006) provides detailed descriptions and specifications for permanently installed (fixed) pedestrian, vehicle, and rail monitors. In addition, the Technical Guide provides details and specifications for supplemental detection equipment such as PRDs, handheld radiation detectors, and neutron detectors. The combined operations of the fixed RPMs, which are typically used for primary detection, PRDs, and handheld detectors for secondary confirmation will be discussed later.

RPMs are designed to be automated and provide high throughput of pedestrians, vehicles, and cargo such that properly designed and maintained systems should not significantly impact traffic for non-alarming situations. The systems are typically installed at restriction points for the normal flow of traffic such as document inspection stations or at a vehicle drop bar. The systems are also designed to minimize additional labor for frontline officers. Officers can typically conduct their traditional activities while the RPM equipment runs relatively unattended. Once a radiation alarm is generated, officers will need to evaluate the alarm, determine if a confirmation inspection is required, and then follow their standard operation procedures to resolve the alarm.

Gamma detection at fixed RPMs

Most RPM locations have gross (total) counting gamma detection equipment using passive scintillating-plastic detectors (e.g., polyvinyl toluene). While the size of the detectors and lane width can vary based on the target object (e.g., pedestrian or vehicle) and the country's risk assessment analysis, most RPMs are based on an opposing two-pillar design, with gamma and neutron detectors on both sides. Vehicle and rail RPMs typically have two detector banks in each pillar to provide coverage for both low (cars) and high (tractor trailers) conveyances. The detectors in the RPMs are shielded from behind to reduce radioactive background and improve detection sensitivity. RPMs may have additional collimators added at locations with high background or where active equipment such as X-rays cause interference because gamma detectors also respond to X-rays.

Most RPMs operate by summing the counts from all detectors and then setting a background level that is automatically adjusted for minor changes in ambient radiation. The RPM detectors work in conjunction with an occupancy (presence) sensor that detects when a target object has entered the detection zone. Once an occupancy occurs, the system fixes the average background and an alarm threshold is then set above the average background (alarm threshold = average background + $n \sigma$, where σ = square root of the background and n is a positive number). The alarm threshold setting is optimized by adjusting the value of n to balance the need for sensitive detection of target materials versus the ability to process nuisance alarms (e.g., false alarms caused by variable background). Decreasing the n value lowers the alarm threshold but increases the probability of a false alarm. Increasing the n value decreases the probability of a false alarm but raises the alarm threshold. The threshold setting also considers the threat basis and site-specific operational limitations. When the alarm threshold is exceeded during movement of the conveyance through the RPM, a radiation alarm occurs and frontline officers are notified by visual, audible, or computer-based notification; this initiates the verification or secondary screening that will be discussed in the alarm response section. Most RPM systems are equipped with video recording equipment and alarms are adjudicated using computer-based software to process and store event details.

Spectroscopic gamma detection equipment

Considerable work has been conducted to design, evaluate, and deploy spectroscopic portal monitors (SPMs) for gamma detection that combine the sensitivity of the gross counting RPMs with a spectroscopic capability to identify radioisotopes ([National Research Council, 2009](#)). SPMs can both detect and identify radioisotopes during a pass through the portal with the potential for higher conveyance throughput and the simplification or possible elimination of a manpower-intensive secondary screening using handheld radiation detectors. SPMs have the potential to reduce the number of secondary inspections for alarms triggered by NORM or medical isotopes. SPMs have been designed using sodium-iodide and high-purity germanium detectors arranged in similar geometries as the gross-counting RPMs. Limitations of the SPMs include higher costs and greater complexity of the equipment, the need for additional training, and higher sustainability costs for maintenance. Currently SPMs are not widely deployed in comparison to the gross-counting RPMs for border security.

Neutron detection

Neutron alarms are especially important because, unlike gamma alarms, there are virtually no natural or background neutron sources. While it might be possible to have a neutron alarm due to a higher background or cosmic event, it is much more likely the alarm is real. The resolution of neutron alarms should be prioritized because they may indicate the presence of nuclear material, specifically plutonium, or the legal or inadvertent transit of a neutron source. While there are legitimate neutron sources such as californium-252 in well-logging equipment or americium/beryllium and plutonium/beryllium neutron sources in commerce, these should always be accompanied by a license and proper shipping documentation. The shipment of large containers of uranium hexafluoride, used to produce commercial power reactor nuclear fuel, provides one of the few examples where a neutron alarm may occur. With this material, neutrons are produced from the fluorine nucleus by interactions with alpha particles from the radioactive decay of uranium (an alpha-neutron reaction).

Helium-3 tubes are the most common neutron detectors and are considered the gold standard due to high detection efficiency, excellent gamma energy discrimination, and non-toxicity. Limitations for helium-3 include its limited supply and that the cost has been rapidly increasing ([Hanson, 2010](#)). Helium-3 tubes are gas-filled stainless steel tubes with a high-voltage wire strung down the middle. The tubes are housed inside a plastic enclosure to slow down (moderate) neutrons to improve detectability. The thermal (slow) neutrons are captured by the helium-3 atoms, which then split into ions that interact with the high-voltage wire and containing wall of the tube to generate an electrical pulse that is counted by the instrumentation. The moderating plastic surrounding helium-3 detectors increases detection sensitivity but effectively limits the ability to measure differing neutron energies. The detectors are not able to identify the specific neutron-emitting radioactive isotopes; however, this is not a major limitation because the

site-specific standard operating procedure should require resolution of any confirmed neutron alarm. In addition, most neutron-emitting isotopes have associated gamma rays that may allow for identification during a secondary inspection using a RID.

Alternative neutron detectors

With the shortage and high cost of helium-3, there have been considerable efforts to develop alternate neutron detectors. Boron-10 and lithium-6 are the leading alternatives. Boron trifluoride gas enriched in boron-10 was commonly used for gas-proportional detectors prior to the widespread use of helium-3 and is a potential low-cost alternative with a similar form factor for the detectors (Kouzes et al., 2009). However, boron trifluoride is a toxic gas and would require some additional mitigation to ensure safe use. Boron-lined proportional detectors have been developed using either a thin layer of boron-10 inside sealed gas-filled tubes or as boron-lined straw tubes (Kouzes et al., 2010a; Knoll, 2010). Detectors using lithium-6 scintillation systems are another promising option (Kouzes et al., 2010b; Knoll, 2010).

Operational factors affecting the sensitivity of radiation detection using RPMs

Many factors affect how well-fixed detection equipment works. Some are intrinsic such as the type and response of the detectors and the amount and nature of the radioisotope. Operationally, the three initial factors to consider for maximizing detection capability are controlling speed of the target past the detectors, optimizing the distance (d) between the detector and the target, and understanding the role of shielding between the target and the detectors. Controlling the speed of the vehicle or person passing through the detection zone increases the time spent near the detector which maximizes sensitivity to radioactive sources. Reducing the distance between detectors and source of radioactivity is particularly important because the intensity of the radiation decreases by the inverse square law ($1/d^2$) and is a major reason why RPMs use parallel detection pillars and data summing. Shielding provides a unique challenge because there is no effective way to reduce the amount of shielding between the detector and radioactive source. Frontline officers need to be aware that shielding may be present and if shielding is suspected, metal detectors, X-ray imaging equipment, or a detailed physical inspection could help confirm the situation. Masking is another situation to consider, where a benign radiation alarm from either NORM, a medical treatment, or a legally transported radioactive source would be used to conceal an illicit shipment by complicating both the radiation detection and inspection processes. Masking scenarios are attempts to make the radiation emitted from smuggled material appear to come from legitimate cargo. For both shielding and masking situations, detection may be possible from a careful and detailed inspection process combined with investigative skills or an information alert.

Handheld gamma radiation detection equipment

Personal radiation detectors

PRDs are small battery powered devices that are highly portable, have fast response, and are easy to operate. PRDs are primarily used as safety devices for frontline officers and are typically worn in a holster on a belt. The devices are set to provide an alarm indication at approximately two to three times background or at a site-specific dose rate; this allows the officers to maintain a safe distance from a radiation source while assessing the dose rate and then proceed according to their site-specific operational plans. A PRD can be used to set up an initial safety perimeter around a conveyance with an elevated dose rate. Most devices use scintillation crystals (e.g., cesium iodide) to detect gamma radiation. For ease of use some PRDs have a simple numeric scale (1–9) or color indicating lights (green, yellow, and red). There is a wide range of supplemental features available for PRDs including higher dose rate detectors (e.g., Geiger-Mueller) and neutron detection (helium-3 or lithium-6); however, due to the small size and limited interfaces, operating agencies should carefully evaluate if these features meet site-specific requirements for higher dose determinations and required neutron sensitivity. The dose rate information provided by PRDs and other handheld radiation detectors are estimated dose only (typically assuming cesium-137 energies) and are not certified dose rate meters.

Handheld radiation detectors and radioisotope identification devices

Handheld radiation detectors are typically larger, heavier, and more sensitive than the PRDs for detecting radioactivity. There is a wide range of handheld equipment used to screen pedestrians and conveyances and all have the general purpose of detecting and determining the location and distribution of radiation (point source or widely distributed). A localized point source usually indicates a discrete source and may be an indicator of illicit activity. A widely distributed source may indicate the presence of NORM; however, officers should be cautious that NORM cargo could be used to mask the signal from an illicit discrete source. Handheld detectors can also be used for officer safety. Radioisotope identification detectors (RID) are handheld devices that identify radioisotopes by analyzing the gamma energies present and comparing them to a library of spectra and most also provide a confidence level associated with the determination. Most RIDs classify the radioisotopes identified into general categories of NORM, industrial, medical, and special nuclear material.

RID detector types vary from thallium-doped sodium iodide [NaI(Tl)] or cerium-doped lanthanum bromide (LaBr₃:Ce) scintillation detectors to semiconductor detectors using high-purity germanium (HPGe). There are pros and cons for each type, with

scintillation detectors typically lower in cost and lighter weight but with only moderate energy resolution. NaI(Tl) detectors are the most widely used due to the relative ease of production and lower cost. The higher cost LaBr₃:Ce detectors have better energy resolution and better scintillation light output (Milbrath et al., 2007; The Royal Society, 2008), but also have an intrinsic background from radioactive lanthanum and actinium impurities. HPGe detectors have excellent gamma energy resolution but need to be cooled and maintained at cryogenic temperatures and are heavier and more expensive than scintillation-based detectors. As with PRDs there is a range of supplemental features available for RIDs that may or may not be appropriate for site-specific requirements.

Integrated alarm response at a border crossing point

Fig. 1 provides a generic depiction of an integrated alarm response for a border crossing point. The flowchart is not intended to be prescriptive but to illustrate some of the challenges and complexity involved during a detection event and is not intended as a replacement for a written site-specific concept of operations. Alarm response starts with the primary detection event, either an instrument alarm or an information alert. For example, a vehicle passing through an RPM at a border crossing point generates a gamma and/or neutron alarm, or for a location without RPMs the detection could occur from an information alert during a passport inspection (e.g., INTERPOL notice).

Either type of alarm would require verification by interviews, inspections with handheld equipment, and/or physical inspection. For simplicity this section will deal with the vehicle scenario. Gamma radiation alarms for small conveyances such as personal vehicles are usually not triggered by NORM because of the limited amount that can be carried. A small conveyance with point sources of gamma radiation could result from legal transport with associated documentation, medical treatment for the driver and/or passengers, or possible illicit transport. Any neutron alarm generated with a small conveyance is highly suspicious and should be confirmed with a second neutron inspection to rule out the possibility of a false alarm from a transient increase in cosmic neutron background. Larger vehicles with commercial cargo or containers have a greater potential to generate NORM alarms in addition to the other alarms discussed above. Radiation alarms can be verified at some locations with an additional pass through the RPM or a pass through an additional RPM dedicated as a verification lane, which can be a valuable tool for neutron verification since it can be difficult to verify small neutron sources with handheld equipment. If the alarm cannot be reproduced with a subsequent pass through an RPM or verified with handheld equipment and no other suspicious observations are present, then the event was likely a false alarm and the people and/or cargo are released.

If the alarm is verified, the officer needs to conduct a hazard assessment and, if safe to proceed, locate the source and determine if the radiation is from a point source or widely distributed. For this discussion an estimated dose rate of $100 \mu\text{Sv h}^{-1}$ at 1 m, a confirmed neutron source, or suspicion of contamination would be a significant hazard and would trigger additional safety

Fig. 1 Generic alarm response flowchart.

procedures, including notification of relevant authorities, initiate measures to isolate and control the source and potential suspects, and activate response procedures detailed in a site-specific plan.

For verified gamma-only alarms with estimated dose rates below $100 \mu\text{Sv h}^{-1}$ at 1 m, the officer can use a RID to identify the radioisotope and determine if the alarm was innocent (medical or NORM) or if an illicit non-innocent alarm has occurred. The officer can also make a gamma-emitting isotope identification without having to open vehicle compartments, cargo, or luggage, which reduces the risk from contamination and other hazards. However, the RID may not provide a high-confidence detection or may report the isotope as “unknown.” In these cases, the investigative skills and training of the officer will be needed to determine if the suspect vehicle and person(s) can be released. The officer may need to contact additional resources from technical experts prior to final release of the alarming conveyance or person. If confirmed non-innocent gamma sources are determined to be illicit sources, the process shifts from detection to response using site-specific procedures to seize the material and/or vehicle, apprehend suspects, provide secure and safe temporary storage of the source and/or vehicle, and initiate any follow-on investigations and legal processes. In most cases the agency that made the detection will need to contact and obtain additional resources from technical experts.

This discussion illustrates some of the complex interactions of officers resolving radiation alarms; however, discussions of high-activity sources, multiple sources, radioactive contamination control, and other hazards (e.g., explosives, physical violence, chemical hazards) are beyond the scope of this introduction.

Sustainability

The risks posed by MORC and efforts to design and deploy radiation detection equipment as part of a national nuclear security detection architecture are significant and require resources to sustain an effective capability. Sustainability planning should include: establishing national and site-level policy and procedures (e.g., concept of operations and response plans); conducting operations in accordance with policies and procedures; maintaining detection equipment and systems; conducting effective training and developing a training cadre; performing programmatic reviews, drills, and exercises to assess and promote continuous improvement of the detection efforts; participating in interagency or international training or evaluation activities; and producing a regular budget-allocated to the relevant agencies and organizations responsible for the sustainment of the nuclear security detection architecture.

Conclusion

The inadvertent or illicit movement of MORC, along with the potential use of radiological and nuclear materials by terrorists, is a real and continuing risk for the global community. Border security efforts to prevent, detect, and respond to these threats are complex and evolving. Radiation detection efforts at border crossing points help to provide an important layer of protection as part of an overall national nuclear security detection architecture and contribute to international nuclear security efforts.

Glossary

Active Interrogation A non-invasive interrogation method whereby a radiation source is used to induce nuclear reactions in a threat object and radiation detectors are used to detect radiation signatures emanating from the induced reaction.

CONOPS The Concept of Operations is the set of steps and procedures that a user follows to employ the detection technique to suit their application.

DDAA Differential Die-Away Analysis is a nuclear material detection method that uses a pulsed source of neutrons and the time dependent nature of neutron thermalization to measure fission prompt neutrons when the neutron source is not emitting neutrons.

DTOF Differential Time-of-Flight technique is similar to the DDAA technique while adding the impact of the thermal (or epithermal) neutron time-of-flight.

ENG Electronic Neutron Generator is a particle accelerator that typically produces either ~2.5 MeV or 14 MeV neutrons through the $d(D,n)He-3$ or the $d(T,n)\alpha$ reactions.

Fissile isotopes U-233, U-235, Pu-239, Pu-241. These isotopes fission by neutrons with any energy, in particular thermal neutrons.

Fissionable isotopes All fissile isotopes plus Th-232, U-238, Np-237, Pu-236, Pu-240. These isotopes can fission by neutrons with energies in the MeV range.

LEU Low Enriched Uranium has a concentration of U-235 of less than 20% (and the rest U-238).

LS A Liquid Scintillator detector is a radiation detector made of a liquid organic compound that creates scintillation light when exposed to radiation. Liquid scintillators can detect both neutrons or gamma-rays. It can distinguish between the two using PSD (see below).

NORM Naturally Occurring Radioactive Materials are objects and materials that contain radiation producing isotopes as a part of their natural composition. Such items include bananas, granite, and certain fertilizers containing potassium.

PBAR Photofission-Based Alarm Resolution system was a successful prototype detection system using a 9-MeV linear accelerator to induce photofission signatures for SNM detection in conjunction to regular high-resolution X-ray radiography.

PFA The Probability of False Alarm is a common metric for evaluating a detection system's performance. It is measured by taking the ratio between the number of times the system alarms on a non-threat object and the total number of times a non-threat object was shown to the system.

PFNA Pulsed Fast Neutron Analysis is a detection technique whereby nanosecond pulsed neutrons are used to induce gamma-ray emitting nuclear reactions in objects to measure their element composition through gamma-ray detectors and their location by considering the neutron time-of-flight and the time of radiation detection.

PNFP Prompt Neutron from Photofission is a detection technique whereby prompt neutrons are measured during the continuous X-ray exposure using detectors and the pulsed shape discrimination (PSD) technique to distinguish between source X-rays and the prompt neutron signature.

PSD Pulse Shape Discrimination is a detection technique whereby both photons and neutrons can be detected in the same scintillation detector but separated due to the fact that gamma-rays interact with atomic electrons inducing a longer decaying light pulse in the detector than the neutrons that interact by recoiling a proton and produce shorter light pulses.

RPM A Radiation Portal Monitor is a radiation detector system used to detect gamma-ray and neutron radiation that are passively emitted from the cargo to screen cargo in vehicles, trains, and other modes of transport.

Sensitivity A general metric used for a detection technique that refers to the strength of the signal and ultimately to the minimum amount or level of material a system is capable of detecting.

SNM Special Nuclear Material is fissile isotope, i.e. Pu-239, U-235 above 20% enrichment, and U-233, from which nuclear devices can be built.

Specificity A general metric used for characterization of a detection technique that signifies how distinctive the detected signal is to a fissile or fissionable isotope. It relates to the technique's ability to distinguish a threat item from a non-threat item.

TAD A Threshold Activation Detector is a neutron detector used for prompt neutron detection. The detector is comprised of a material that activates when exposed to neutrons above a threshold energy. The detector measures the level of its self-activation as a signal for prompt fission neutrons.

TOF Time-of-Flight refers to the time of flight of a particle from its origin to its point of detection.

Voxel A volume element within an inspected object's volume.

Introduction

In the previous chapter (Patton, 2021), current technologies for addressing border security and public safety in the international arena were presented. They included radiation portal monitors (RPMs), handheld dosimeters, and X-ray inspection. These technologies have been widely deployed throughout the world because they are relatively easy to use and they are relatively inexpensive to acquire and operate. They provide the end user with valuable tools for interdiction of threats in cargo conveyances. However, these tools do have their limitations as the complexity and density of the cargo and types of threat become greater.

For border security applications, there are three primary methods for screening cargo for threats of interest. The major threats are explosives, narcotics, radiological material, and Special Nuclear Material—SNM. The relative merits of the three methods of detection (Passive Detection, Radiography, and Active Interrogation) are dependent to a large extent on the cargo material being screened. As the cargo complexity, density, and atomic number (Z) increase, the effectiveness of one method is reduced and is better addressed by another one. A notional diagram outlining this relationship is shown in Fig. 1.

The simplest method, Passive Detection, was described in Patton (2021). Passive Detection may be sufficient for screening cargoes of low complexity and density. As these factors increase, the radiation signatures (either photons or neutrons) are more effectively attenuated by the cargo and, thus, cannot be detected. One should note that Passive Detection is only applicable to

Fig. 1 Notional relationship between detection performance and cargo complexity for the three main technology areas (Passive Radiation Detection, low and high X-ray Radiography, and Active Interrogation).

detecting radiological material. This method has no relevance to detecting other threats such as narcotics and explosives. Moreover, it has only limited capability in detecting SNM.

The second method, X-ray radiography, provides the screener with a visual interpretation of the cargo by way of an X-ray image. Thus, the screener can make a better determination of the cargo contents, potential hiding locations, and a more accurate measurement of dense objects in the cargo. However, X-ray imaging does not provide specific identifiable evidence of radiological material, SNM or other threats. This method only provides indications of the presences of dense objects or objects with relatively high atomic numbers that are commonly used for shielding gamma-ray sources or SNM.

To overcome this deficiency, one can use the third method, active interrogation. This method uses an ionizing form of radiation to induce nuclear reactions in the threat material. The radiation signatures emanating from the reactions are then sensed by detectors. In some cases, active interrogation can be utilized in concert with passive radiation detection because the signatures can be collected with the same radiation detectors. Similarly, active interrogation can be deployed with high energy X-ray Radiography because detection signatures can be induced by the same high energy X-ray source deployed for radiography. Active Interrogation methods are advanced technologies offering capabilities that are lacking in existing technologies but are challenged by relatively high cost, large size, and implied complexities. However, the significant benefits in detection performance make it worthy of exploration in this chapter.

Fission signatures and basic physics of active interrogation

Active Interrogation is a category of screening techniques that utilize a radiation source to induce a unique detectable signature in the material of interest. In contrast to passive techniques that rely on the material alone to provide the detectable signature, active techniques rely on a nuclear reaction between the interrogating radiation source and the material to provide the radiation signature to detect the material. In general, active interrogation techniques are considered more difficult to field. However, they provide performance advantages not achievable with the passive techniques. The radiation sources used for active interrogation range from high-energy X-rays (6 MeV or higher) and neutrons (thermal to 14 MeV). Choosing the radiation source type for the application is a trade-off on complexity, size, performance, and cost.

X-rays interact with matter by way of the atomic electrons. X-rays are either absorbed, scattered or disintegrate after interacting with the atom. In general, the interaction rate with matter is a strong function of atomic number Z ($\sim Z^4$) in the “Photoelectric effect” domain at X-ray energies below 1 MeV. The interaction rate has very little to no Z dependence between X-ray energies in the “Compton” domain of 1–5 MeV. At X-ray energies above 5 MeV, the interaction rate is a strong function of Z ($\sim Z^2$) in the “Pair Production” domain. As a result, X-ray attenuation increases with increasing Z and atomic density. Thus, denser higher- Z materials like lead and tungsten attenuate X-rays to a larger degree than less dense lower- Z materials like plastic and water. It is for this reason that lead is typically used for X-ray radiation shielding.

A neutron is a subatomic particle with no charge and a rest mass energy slightly higher than a proton (939.6 vs. 938.3 MeV). To understand the physics on a neutron’s interaction with matter, it is helpful to do a thought experiment using billiard balls. Due to their similar mass, we can represent a neutron as one ball and a proton as another. If one ball is at rest and the other collides with it, the former imparts a percentage of its kinetic energy to the latter that is dependent on the angle of scattering. Because the masses are similar, the former will impart all of its kinetic energy to the latter with a head-on collision. This is analogous to a neutron interacting with a proton, or in a familiar case, with a hydrogen nucleus consisting of one proton and no neutrons. On average, a neutron loses half of its kinetic energy when colliding (and being scattered) by a hydrogen nucleus. The heavier the element (assumed at rest) the neutron collides with, the smaller will be the fraction of the neutron kinetic energy that is imparted to that element, thus reducing its own kinetic energy. This process is commonly referred to as the Slowing Down process in the field of nuclear physics. The last stage of this process is called Thermalization, in which the neutrons and target nuclei have a comparable kinetic energy. Neutrons will thermalize in smaller number of collisions and, hence thermalize faster in cargo comprised of lower- Z materials (plastics, water, and oil) compared to the higher- Z materials (machine parts, appliances, and cement). This difference in the way that X-rays and neutrons interact with matter is important when considering the effectiveness of active interrogation. X-rays and neutrons are used as sources for this technique. A significant number of the source particles needs to penetrate any cargo that is present before inducing a detectable signature in the material of interest.

The signatures of interest for the detection of SNM are initiated by the fission process. Fission is nuclear reaction whereby a nucleus splits into two lighter nuclei (Klay, 2020). Fission occurs as a result of the competition between the strong nuclear force (that binds the protons and neutrons of a nucleus together) with the Coulomb force (that repels like charged particles away from one another—in this case protons with positive charge). This reaction occurs when a photon or neutron of sufficient energy interacts with the nucleus of a heavy element (thorium and higher) to create a compound nucleus with excess energy that results in splitting into two unequal isotopic nuclei rather than remaining as one. A key parameter for fission based SNM techniques is the magnitude and energy of the interrogating radiation’s dependence of the fission cross section (see Table 1). It expresses the ability of the interrogation radiation to induce fission in the nuclear material. It varies greatly with energy and the type of the probing radiation. For example, U-235 fission cross section ranges from close to 600 b (barn = 10^{-24} cm²) for thermal neutrons, 300 b for the resonance neutrons (0.4–10 keV) down to about 1.2 b for fast neutrons. It is much lower for the photofission process, about 0.001 b at 6 MeV rising to about 0.1 b at 10 MeV photons.

Table 1 Fission cross-sections of long-lived fissile and fissionable isotopes (JAEA, 2020). Values without units in the table are in unit of b (barn).

Isotope	Thermal (0.0253 eV)	Resonance integral	Fission spectrum
^{232}Th	54 (μb)	375 (μb)	80 (mb)
^{233}U	531	775	1.91
^{235}U	585	274	1.22
^{238}U	17 (μb)	1.2	0.31
^{237}Np	20 (mb)	5.37	1.34
^{238}Pu	17.77	27.76	1.97
^{239}Pu	747.4	301	1.80
^{240}Pu	36 (mb)	8.13	1.30
^{241}Pu	1012	567.4	1.63

The fission cross section of Pu-239 has a similar behavior but it is higher by about a factor of 1.1–1.5 than that of U-235. Most other actinides isotopes (e.g., Th-232, U-238, Np-237, Pu-240) undergo fission only by higher energy neutrons (having thresholds above about 0.1 to 1 MeV) but not by thermal neutrons.

Signatures from fission can be grouped by their emission time relative to the fission event and are typically referred to as either prompt or delayed events. The signatures are prompt neutrons, prompt gamma-rays, delayed neutrons, and delayed gamma-rays. Each will be described here.

The prompt neutrons and gamma rays are emitted instantaneously—at the moment—of fission. They are among the strongest signatures available: about 2.4 and 4.5 n/f, corresponding to fission by thermal and 14-MeV neutrons, respectively. On average, about 3 n/f are generated in photofission with X-ray end point energy of 9 MeV (see Table 2).

For prompt signatures, the background radiation due to the interrogation particles is always very high and often overwhelms the detectable signal. In order to detect the prompt neutron signature, in the presence of such a high background, one attempts to discriminate between the two by suitable shielding and some sort of energy and/or temporal or multiplicity discrimination.

The prompt gamma ray signature emitted in the fission process is also a very strong signature. On average, close to seven photons are emitted in the fission process. Unfortunately, it is very difficult to use the prompt gamma ray signature because of the presence of the very strong gamma-ray background from the source neutron interaction with structural and cargo material (when neutron interrogation is used) or the X-ray field (when X-ray interrogation is used). All gamma detectors are generally blinded during the period the interrogation source is on and, hence, could not detect the prompt fission photons. Thus, no practical active interrogation technique is based on detecting prompt gamma-rays from fission. The exception is Pulsed Fast Neutron Analysis (PFNA) that is described in more detail later in this chapter. In this technique fissionable materials are detected via the prompt gamma ray signature employing the time-of-flight method afforded by its nanosecond neutron pulsing capabilities.

The delayed fission signatures (delayed neutrons and delayed gamma-rays) originate from the chain of beta decaying fission fragments (and their daughters). As such, they can be measured well *after* the fission events occurred when a much lower source related backgrounds exist. These signatures, in terms of both absolute intensity and their pattern of temporal decay, are unique to the fission process of the specific actinide isotope. It is common to group the fission fragments that emit delayed neutrons in six groups characterized by the radioactive decay half-life (Previtali, 2021). The absolute delayed neutron yields and their six time-groups for neutron fission are given in Table 3. The same quantities for photofission are given in Table 4. The yield increases slightly as the energy of the photon inducing fission increases. The delayed neutrons are easy to detect, but they suffer from low intensity and lower energy (average ≈ 450 keV), which make them susceptible to absorption, especially in hydrogenous cargo.

The absolute delayed gamma-ray yield and their five time-groups are given in Table 5. These quantities are, within the current experimental accuracy, applicable to both neutron fission and photofission. There are many tens of beta decaying chains of fission products with half-lives from milliseconds to thousands of seconds with multitude of excited states. There are a few weak discernable isolated gamma-ray lines that can be used as a detection signature. However, a much more useful signature is to measure the much stronger and readily detectable gross delayed gamma-ray spectrum. This spectrum (above a few tenths of an MeV) has an exponentially declining intensity vs. energy. The value of the negative energy exponent is roughly 1.1 ($\pm 10\%$). Most of the delayed gamma-rays are emitted within a few minutes, significantly slower than the delayed neutrons, most of which are emitted within 10–

Table 2 Average number of prompt neutrons emitted in fission by neutrons and photons (Caldwell and Dowdy, 1980; Gozani, 2009a, 2009b; JAEA, 2020; Verbeke et al., 2014).

Isotope	0–14 MeV neutrons in neutron fission (n, f) reaction	9 MeV Bremsstrahlung in photofission (γ, f) reaction	Number of higher energy fission neutrons with energy > 3 MeV for (n, f) or (γ, f) reactions

20 s after the fission event. However, the intensity of delayed gamma-rays, even the high energy fraction above 3 MeV alone—about 2–3% of the total—is order of magnitude higher than the total delayed neutron yield and is much more penetrating in hydrogenous cargo.

The continuous non-discrete shape of the delayed gamma-ray spectrum allows the use of detectors with a mere medium or even poor energy resolutions (like plastic scintillators). This, in turn, allows lower cost large area detectors (Slaughter et al., 2007; Han, 2021) to be employed making the high energy fission delayed gamma-rays a very attractive and practical fission signature.

Signatures to detect nuclear material through active interrogation have been described in this section. The practical techniques that have been demonstrated to identify the presence of nuclear material, either through measuring of the signature itself or measuring a property of material that indicates its possible presence, will be covered in the next sections.

High energy X-ray inspection

X-rays were discovered by Wilhelm Conrad Roentgen in 1895 when he observed a glowing plantinobarium screen several feet away from an experimental study of glass bulb electrodes. One of his earliest images using these X-rays was of his wife's hand showing her wedding ring clearly in one of the most famous images (Fig. 2) in history (Riesz, 1995).

Fig. 2 One of Roentgen's first X-ray image.

Since that time, X-rays have been used in the fields of medicine, industrial sterilization, non-destructive testing and security (Waltar, 2021; Bjornstad, 2021a). Some of their uses may be well known to the reader; others may not. In hospitals and dental offices, an X-ray system is used to image bones and teeth of patients. These images are produced using an X-ray generator on one side of the patient and an X-ray detector (phosphorescent screen or digital x-ray detector) on the other side. The level of X-ray transmission through the body part of interest is dependent upon primarily its density and secondarily its composition, including, bones, fat, muscle, and other tissue. X-rays are either absorbed or scattered to a higher degree by objects with higher atomic numbers (Z) and higher density. For molecules, it is common practice to calculate the effective atomic number (Z_{eff}) based on the chemical formula and the atomic numbers of the elements in the molecule. Thus, when an X-ray interacts with a bone (comprised of mainly calcium) with $Z_{\text{eff}} = 13.8$, it is preferentially attenuated to a larger degree than an X-ray that interacts with muscle ($Z_{\text{eff}} = 4.5\text{--}6$). This differential attenuation of the X-rays results in a higher number of them detected in line with the muscle and tissue versus the bone. This provides a contrast in the image that shows the bone clearly as an X-ray "shadow" that shows the structure of the bone.

The use of X-rays in port and border security is a more specialized field. X-ray inspection is a common technique used at cargo seaports and land ports of entry. At these facilities, entire shipping containers are unloaded from ships in under a minute. In some customs applications, a select number of containers are set aside and screened by customs officials using X-rays to look for contraband materials or instances of duty violations. To screen an entire shipping container that typically contains a wide range of material (tires, engines, computers, tile, furniture, and clothing to name a few), the X-ray screening system typically uses an energy of 4.5 MeV or higher. Typical medical X-ray systems use X-ray energies between 20–150 keV. The energy level for border security is 2–3 orders of magnitude greater, but the general process is similar. The X-rays are produced from an X-ray source. In this case the source is usually a linear accelerator (linac) (Varex, 2020) or a betatron (JME, 2020; Garcia, 2021) capable of producing X-rays by accelerating electrons into a metal target with high atomic number (typically tungsten or a tungsten alloy). These X-rays are collimated into a beam shaped like a fan. X-ray detectors reside on the opposite side of the container to detect those X-rays that penetrate and transmit through the container and its contents and impinge on the detector. A diagram of the basic geometry and subsystem components is shown in Fig. 3.

Material contrast is generated by the structure and composition of the objects being screened. In the cargo screening application, the object being scanned is often a cargo container. The X-ray source is used to provide material contrast using a technique called dual-energy imaging. In this imaging modality, the X-ray source alternates between two different X-ray energies from pulse to pulse separated by 3–20 milliseconds. As a result, two X-ray images are created for the same container and its contents. Due to the Z -

Fig. 3 Schematic of a standard X-ray imaging system used at land and seaports.

dependence on absorption and scattering, the two images provide two different energy dependent data points on the attenuation of objects in the image. These systems are calibrated in the factory with several different materials of known Z to determine the X-ray detector response to the two different X-ray source energies. In the field at a land border crossing or seaport, the system images containers where the contents and material composition are unknown. After the two X-ray images are produced, the Z -calibration from the known objects is used to roughly estimate the Z of the unknown objects.

Special nuclear material (SNM) of interest is comprised mainly of uranium or plutonium. Unlike other methods described later in this chapter, X-rays do not have the ability to specifically identify the presence of U or Pu through transmission imaging alone. Also, the X-ray detectors are not measuring the presence of radiation emanating passively from the SNM with detectors as described in (Patton, 2021). Instead, X-rays screening can provide some material contrast to a broad level. Due to their high Z (92) and high density (19 g/cc) for uranium, SNM, as well as possible shielding materials such as tungsten ($Z = 74$) or lead ($Z = 82$), are highly attenuating to X-rays of energies used in cargo screening techniques. As described above, these high- Z objects will show as a darker object on the image because very few X-rays penetrate through the object and are detected by the detector array. Vendors providing screening equipment to a Customs organization typically provide a color overlay on the image to guide the user's eye to different materials of interest. Organic materials with lower Z will have one color, while metals of higher Z will have another color. The presence of a dark object with a high- Z overlay color could then be possibly indicative of SNM, tungsten or lead shielding. However, a similar-looking image object could also be created by thicker material of lower- Z (such as steel) that is directly in line with the X-ray beam path between source and detector.

The ability to inspect the cargo depends on the ability of the X-ray beam to penetrate the cargo. The higher the X-ray source energy, the greater the penetration and the greater range of cargo can be inspected. Fig. 4 demonstrates the effect that beam energy has on cargo penetration. Notice that the entire cargo is revealed in the 9 MeV X-ray image, whereas areas of the cargo shown in red are not penetrated at lower energies. For cargo inspection, the highest energy currently allowed by the World Health Organization is 10 MeV.

Fig. 4 Examples of cargo penetration vs. photon beam energy.

Transmission imaging alone cannot unequivocally determine the presence of SNM. Additional techniques are required and can in principle be used in concert to provide the information required to be more certain of the suspicious object's material.

Novel techniques and prototype technologies have been studied and developed to work with transmission X-ray screening by utilizing additional signatures emanating from the cargo material interactions with the high energy X-rays.

One technique measures the energy spectrum of the transmitted X-rays using energy sensitive detectors. Traditional methods measure the electrical current induced by the X-rays inside the detector. We already learned that X-ray attenuation is dependent on the type of material attenuating it and the X-ray energy. The linac sources emit X-rays with a broad Bremsstrahlung energy spectrum. The deviation in the shape of the X-ray energy spectrum can provide information about the material being interrogated (Gozani et al., 2014). The effect that a material (of known atomic number) has on the X-ray energy spectral shape is shown in Fig. 5. The energy spectrum of the transmitted X-ray beam through the higher Z material is far richer with lower energy X-rays than in the lower Z material case. A spectral ratio can be calculated by taking a ratio of the low energy spectral region to that of the high energy region. A strong Z dependence is revealed as shown in Fig. 6. Key issues with fielding this technique are the required level of collimation, the large background of multiple scattered Compton photons, and the need to have a stable very fast detector to handle a large dynamic range of count-rate.

Another high energy X-ray technique that provides high Z material detection is based on the high-energy Bremsstrahlung back-scattered radiation (Van Liew et al., 2017). The interrogating X-ray beam generates Compton electrons (and to a lesser extent electron-positron pairs) in its direction as part of its attenuation process by the cargo materials. Many of these electrons undergo multiple collisions with the cargo atoms and a few alter their direction of motion from forward (the X-ray beam direction) to backward direction. These electrons lose energy in part by the Bremsstrahlung process, emitting high energy X-rays that can be detected

Fig. 5 Bremsstrahlung X-ray spectral shapes after cargo transmission vs Z at a fixed attenuation level.

Fig. 6 Atomic number Z as a function of a spectral ratio of low to high energy regions in the transmission X-ray energy spectrum.

by energy sensitive detectors placed at the back angles ($>90^\circ$). The normal backscattering spectrum of Bremsstrahlung radiation is made up of low-energy photons with a maximum energy of 0.256–0.511 MeV (corresponding, respectively, to photon scattering by 180° -backscattering- and 90° scattering). These low energy backscattered X-rays are highly absorbed in cargo material limiting their usefulness for cargo examination to near the surface of the cargo container. There exists, however, a small but noticeable high-energy component (resulting from the Bremsstrahlung process mentioned above) in the X-ray backscattered spectrum that is significantly stronger for high-Z scatterers like tungsten and uranium. These processes are strongly Z dependent (about Z^2). These characteristics can provide a strong indication for high Z material presence. The intensity of the high-energy backscattering signal above 1 MeV for tungsten in air is estimated to be 10^{-12} to 10^{-11} photons/cm²/electron.

The strong Z dependence of the backscattered secondary electron Bremsstrahlung spectrum, expressed by the ratio of low energy part of the spectrum (<0.6 MeV) to that of the high energy measured by NaI detector for 6-MV linac, is shown in Fig. 7.

The Z information gleaned from this method is stronger at 9 MV, as the high energy flux of the Bremsstrahlung is far richer with high energy photons. The main strength of the technique is the strong dependence of the backscattered intensity on the Z of the scattering object. The main drawback of the method is the necessity to use a very strong X-ray source, a large array of efficient and highly collimated medium resolution detectors (such as NaI), and the need to employ a rastered narrow X-ray beam (Van Liew et al., 2017). The intersection area of the beam with the projection of detector collimation area defines the pixel of the scattering material. The motion of the cargo provides the third dimension, defining the voxel of the scattering volume.

High energy X-rays above 6 MeV (though practically >8 MeV) can interact directly and uniquely with SNM via photofission. The process generates unique signatures, like prompt and delayed neutrons and gamma-rays, which are measured with appropriate detectors. Neutron and photofission-based inspection techniques are discussed in the next sections.

Neutron-based inspection techniques

In the previous sections, technologies based mainly on the detection of the high atomic number (Z) and density of materials were described. These properties are characteristic of nuclear materials and their potential shields (such as tungsten or lead). In this section, active neutron interrogation technologies based on one or more fission specific signatures of nuclear materials are described. General papers on neutron interactions, sources and detectors and industrial applications can be found in Bjornstad (2021b), Theresa and Brisset (2021), and Han (2021). Overview publications on neutron and photon-based inspection can be found in Gozani (1981, 1985, 1996, 2010) and Runkle et al. (2012).

Neutron-based inspection techniques are considered to be the most versatile for probing the elemental composition of materials. Fast (>100 keV), epithermal (100 keV–0.4 eV) and thermal (<0.4 eV) neutrons interact with almost all isotopic elements existing in nature, generating characteristic gamma rays, indicating the presence of these isotopes, and by inference that of the corresponding elements. Thus, neutrons can and do detect the presence of explosives, narcotics as well as other substances and nuclear materials, specifically SNM. The latter can be detected very well also by linac-based photofission (see the following section).

Fig. 7 High energy backscattering spectral ratio vs. Z.

Neutrons are generated as a result of charged particle interactions. The most common neutron producing reactions are the exothermic (d,D) and (d,T), where the accelerated projectile is a deuteron and the target is titanium (or similar metal capable of absorbing hydrogen isotopes like deuterium or tritium). The resulting neutron energy is 2.5 MeV and 14 MeV, respectively. The (d,T) reaction yields about 100 times more neutrons per deuteron than the (d,D) reaction at the low accelerating voltage of 100 keV, where most commercial neutron generators operate. The d-D generators, (depending on design, size, cost etc.) can yield neutron intensities of the order of 10^6 – 10^{10} n/s. The d-T generators yield 10^8 – 10^{13} n/s. These accelerators can provide continuous or pulsed beams with a pulse width as narrow as ≈ 5 μ s and with practically unlimited repetition rate (all the way to a continuous beam).

Neutrons of different energies interact differently with the target nuclei. Fast neutrons interact mainly via inelastic scattering process, where the colliding neutron loses part of its energy and the collided nucleus deexcites by emitting characteristic gamma rays related to its specific nuclear structure. Thermal and epithermal neutrons interact mainly via neutron capture process. Here the colliding neutron is captured by the nucleus that is converted into another nucleus. The two nuclei have the same number of protons but the product nucleus has one more neutron. The two nuclei pertain to different isotopes of the same element. The product isotope is created in an excited state, which then deexcites by emitting characteristic gamma rays. Generally, the capture gamma rays have higher energies (some exceeding 10 MeV) than those generated by the inelastic scattering process. Carbon, nitrogen, and oxygen are exceptions. They have very low thermal neutron capture cross sections but with a substantial fast neutron inelastic cross section resulting in relatively high inelastic gamma energies (2–7 MeV).

All neutrons from zero energy and above can induce fissions (with declining cross sections vs. energy) in fissile isotopes (i.e. SNM). All fissionable isotopes can undergo fission by fast neutrons with energy above roughly 1 MeV. Thus, any neutron-based technique can, in principle, offer detection of fissionable material as well as other threats such as explosive and narcotics. The very high fission cross section of thermal neutrons ($\approx > 600$ b), the strength and specificity of the fission signatures, result in a much higher probability of detection of SNM per gram than that for explosives.

Current technologies

The list of neutron-based technologies relevant to the Active Interrogation (AI) of nuclear materials available or being developed is provided below in Table 6.

Table 6 Main neutron based active interrogation (AI) techniques for SNM

#	Technique name	Probing radiation	Source	Signature	Detectors	Specificity/sensitivity (applicable to)
1	Differential Die Away (DDAA, DTOF)	Thermalized neutrons	Any pulsed ENG (most common (d,T), (d,D)), pulse width $\approx 100\mu$ s	(n_p) and secondarily (n_d)	(1) Moderated neutron detector (^3He & or similar) (2) LS + PSD (3) NaI	Very high/very high (fissile and other threats w/NaI)
2	Delayed gamma rays (γ_d & $\gamma_d(t)$)	All $< 10\text{MeV}$ neutrons inducing fission	$E_n < 10\text{ MeV}$ e.g., (d,D), time switchable (e.g., 5s on/5s off)	Gross delayed γ rays (amplitude & time dependence)	PS or LS, (CsI, LaBr ₃)	Medium high/high (fissionable)
3	Direct prompt fast neutrons (n_p)	Neutrons with $E_n < 3\text{MeV}$	(d,D)	n_p w/ $E_n > 3\text{MeV}$	TAD, LS + PSD	High/medium (fissionable)
4	Delayed neutrons (n_d & $n_d(t)$)	All neutrons inducing fission	Any switchable source (e.g. 5s on/5s off) such as shuffling ^{252}Cf , (d,T) or (d,D) ENG	Delayed neutrons $n_d(t)$ (amplitude & time dependence)	Moderated ^3He or similar detectors based on ^{10}B or ^6Li	Very high/very low (fissionable)
5	Time correlation techniques (FMD, Rossi α, Feynman, etc.)	Slowed down neutrons and/or neutrons with $E_n < 3\text{MeV}$	CW (d,D)	n_p , γ_p	PS, LS + PSD, Moderated neutron detectors (^3He & or similar det.)	Medium high/low (fissionable)
6	Pulsed Fast Neutron Analysis (PFNA)	Monoenergetic fast neutrons in the energy range of 7–9 MeV	ns pulsed (d,D) in frequency range of 1kHz to 1MHz rep rate	$(n, n'\gamma)$ & γ_p from (n,f)	PS or LS with very fast timing	High /high provides 3D localization for fissionable and other threats such as explosives
7	API (Associated Particle Imaging)	14 MeV-n in coincidence w/ the associated α particles	CW (d,T) + embedded α detector	$(n, n'\gamma)$ & γ_p from (n_{14}, f)	NaI (LaBr ₃)	Medium high/low provides limited 3D localization for fissionable and other threats as explosives

ENG, electronic neutron generator; CW, continuous wave (not pulsed); DF, duty factor; PS, plastic scintillator detector; LS, liquid scintillator detector; PSD, pulse shape discriminator; TAD, threshold activation detector; FMD, fission multiplicity detection; Rossi and Feynman are data analysis methods to derive the system's neutron multiplication.

The table lists the main techniques that are based on neutron interrogation. Key features of each technique are provided, including information on the neutron source, the main fission signature or signatures used, the means of detection employed, and two qualitative attributes of the technology: “Specificity” and “Sensitivity”. Specificity relates to the uniqueness of the measured signals to fissile or fissionable materials. For example, delayed neutrons have very high (possibly the highest) specificity, as no other materials in nature besides the fissionable ones (with a very few and rare exceptions) emit this type of delayed radiation. Sensitivity relates to the strength of the specific signature or signal and its other attributes (such as energy) that affects their penetrability through cargo. For example, the number of delayed neutrons emitted per fission dictates the magnitude of the measurable fission signature. This, in turn, determines the number and size of the detectors required to measure it within operational constraints.

An effective system is one that has high specificity and sensitivity. When quantified, the product of the two may define the system’s “effectiveness.” The table lists the technologies (#1–#7) in the rough order of their “effectiveness” from high to low. In actual AI systems, multiple complementary techniques are employed together to enhance the robustness of the overall interrogation system.

A brief synopsis of active Interrogation techniques available or being developed is provided below.

Differential die-away analysis (DDAA)

DDAA is a method to detect prompt neutrons emitted during the fission process induced by thermal neutrons only in fissile materials, such as U-235, Pu-239 (Caldwell et al., 1986).

Thermal neutrons are created by the slowing down and thermalization of a pulse of fast neutrons (i.e. from an electronic neutron generator). These processes occur rapidly within a few microseconds. Once the neutrons have thermalized, their population can remain for a long time period of a fraction of millisecond to a few milliseconds, depending on the moderating and absorption properties of the medium. These processes occur in the moderating material surrounding the source (by design) and/or inside the inspected object if it contains hydrogenous substances (e.g., cargo composed, among others, of organic materials). A fast neutron detector with a fast response time will see no signal after a short time of a few microseconds if no fissile material is present. A slower fast neutron detector, such as a He-3 detector covered with cadmium (to capture thermal neutrons), having intrinsic “die away” of 20–40 μ s, would not see any neutrons after about four die-away times (from 80 to 160 μ s). The thermal neutron population in the moderating material, however, can last for relatively long time and decays with time constants of the order of a few 100 μ s to a couple of milliseconds. If fissile material is present, fissions will be induced and fast prompt fission neutrons will appear and be detected by the DDAA neutron detector. The detection of this relatively slow decaying fast neutron population is an unequivocal indication to the presence of fissile material in the inspected object.

The DDAA technique is a very sensitive SNM detection technique because of the very high fission cross section of thermal neutrons in fissile materials and the high efficiency with which these neutrons can be detected.

There are variants of the DDAA technique (Jordan and Gozani, 2007) that have been adapted for specific inspection scenarios, such as the inspection of large bulky objects like 20/40-ft (6.1/12.2 m) shipping containers used in maritime and land transport. Another variant is the DTOF (Gozani et al., 2013) technique that is the manifestation of the DDAA technique when the inspection object is at a significant standoff distance (e.g., > 0.5 m) from the source. In this case, the thermal (and epithermal) neutron time-of-flight from the source to the object is to be considered in the detection process. Recently the DDAA technique was extended to demonstrate the feasibility to detect SNM with more penetrating epithermal and even sub-MeV neutron fraction of the 14 MeV slowing down spectrum (Gozani and King, 2016, 2017). However, these require an intense narrow-pulse (< 100 ns) dT neutron generators with high frequency pulsing, which are not available commercially.

Several different systems based on thermal neutron inspection have been built. An example is shown in Fig. 8. The system in the figure was designed to detect explosives by looking mainly for a high energy gamma-ray from the de-excitation of nitrogen (10.8 MeV). When cadmium covered banks of moderated He³ (or other thermal detectors) were added (see Fig. 9) highly sensitive DDAA capability was added to detect SNM. Furthermore, a large area thermal neutron detector array added above the inspected conveyance increases significantly the detection sensitivity of delayed neutrons. Typical raw signals from such a system are shown in Fig. 10.

Delayed gamma-ray based inspection system (Stevenson et al., 2011)

This technique detects the presence of fissionable material through the detection of the gross gamma rays emitted by the fission products from a fraction of a second to many seconds after the fission event.

The fission processes (induced by either neutrons or a high energy photons) in all fissionable isotopes generate a copious number of gamma rays. Though the majority have low energies, a useful fraction of a few percent is above 3 MeV. The decay times of the delayed gamma rays cover a wide range: from milliseconds to many seconds. The practical time range is from a few tenths to tens of seconds. The optimal irradiation/counting sequence is typically 5–10 s irradiation (i.e. source “ON”) and a similar time for counting (source “OFF”). In pulsed mode the delayed gamma rays appear conveniently as constant background between pulses following the complete decay of the capture gamma rays in a few milliseconds after the end of the neutron pulse.

Delayed gamma detection techniques can be employed with both neutron and high energy X-ray sources. The sources can be inherently pulsed (like linac or pulsed ENG) or continuous. To detect the delayed gamma-rays, the source (if not pulsed) is sequentially turn on for a few seconds and then off for a similar time. When the source is off, the detector acquisition is turned on to detect

Track mounted dual sided VEDS system inspecting a truck

Fig. 8 A gantry active neutron interrogation system for inspecting trucks designed and built as VEDS (Vehicular Explosives Detection System) by Ancore Corporation.

Fig. 9 Combined Explosive and Nuclear Detection system (Dual VEDS/SNMDS). A basic platform for all key neutron-based inspection techniques. The truck is being inspected simultaneously from both sides.

the delayed gamma rays. This process is repeated until sufficient statistical precision of the signal is achieved. The detector does not require having a particularly high energy resolution, as the gross delayed gamma spectrum is basically “featureless” that exponentially declines with energy; with an average energy of about 1 MeV (see Fig. 11).

The signal to background ratio for the high energy part of the spectrum, above most of the natural gamma-ray background (>2.6 MeV), is a strong indication for the presence of a fissionable material (hence, “good specificity”). The intensity of the signal is generally high when employing reasonably strong sources and large area efficient gamma ray detectors (hence, “high sensitivity”).

Fig. 10 Basic response of DDAA detector to fissile & fissionable material. Please note that the depleted uranium DDAA response is from the residual U-235. The delayed neutron response however is due to thermal fission of the residual U-235 and fast fission in U-238.

Fig. 11 Measured gross delayed gamma-ray spectrum.

The dominant background for the gamma ray signal is very different from that in the neutron detection modality and is much higher. It consists of thermal neutron-capture gamma rays (which, for example, enable explosive detection), which decays with the time constant of the thermal neutron flux (hundreds of μ s to ms) after the source pulse. The second background source is due to the possibility of neutron activation of any cargo present or of structural materials. This is the reason that it is difficult to use 14 MeV neutrons as an interrogation source if the delayed gamma rays are to be employed as a fission signature (Slaughter et al., 2007). The

14 MeV neutrons activate O-16 atoms via the (n, p) reaction with a threshold at 10.2 MeV. The reaction product, N-16, decays back to O-16 by emitting a β ray and a 6.1 MeV photon, with a half-life of 7.1 s. This activation can constitute a significant background, since oxygen-containing materials are very common in cargos. A third background is the background due to naturally occurring radioactive materials (NORM), which is significant at or below 2.6 MeV, emanating from the natural radioactivity of the soil and the environment in general. A fourth source of background, for this measurement, is passive radiation from the LEU sample itself. Thus, a commercial d-D ENG is the recommended option when a delayed gamma ray signature is crucial. No significant extraneous cargo activation occurs since the d-D neutrons are limited to energy of about 2.5 MeV. Unfortunately, the available neutron yield for d-D ENGs is still relatively low of the order of 10^8 n/s. More powerful generators for 14 MeV and lower energy (Slaughter et al., 2007; Phoenix, 2020) are larger and more expensive. Delayed fission gamma rays are arguably the most effective fission signatures in a photofission-based inspection system employing low neutron background electron linacs (see next section).

Direct prompt fast neutrons

This technique measures directly the high energy tail of the prompt neutron spectrum emitted during the fission process. Any penetrating particles (e.g., neutrons or high energy X-rays) that cause fission can be used as an interrogation source. Fast neutron detectors, which are able to discriminate between the numerous source particles and the higher energy fission neutrons and can be effectively shielded to cope with the inevitable severe “source flash,” are employed in this technique.

On average, about three fast neutrons/event are emitted during fissions induced by thermal neutrons. This number increases slightly as the energy of the neutrons increases. Thus, detection of fast fission neutrons during the fission process is a strong positive indication for the presence of a fissionable isotope (hence, it has “high specificity”). The discrimination between the two types of neutrons (i.e. between the fission neutron signal and the numerous background neutrons and X-ray photons), while retaining a good detection efficiency and ability to function during the “source flash,” are major challenges in this direct prompt fission neutron detection method. The energy of the source neutrons must be lower than at least that part of the high energy tail of the neutron fission spectrum one wishes to detect. The d-D ENG emitting neutrons with $E < 2.8$ MeV (highest energy at zero degree) is the highest source energy that is typically employed. The fission spectrum above 3 MeV still contains about 25% of all fission neutrons. X-rays with energy below 9 MeV produce in cargo mostly lower than 3 MeV background neutrons, via photoneutron interactions—mainly in the deuterium, which is always present in hydrogenous substances. These high energy X-rays are therefore very useful for interrogation for fissionable materials (see next section). The neutron detectors must be able to discriminate between the numerous < 3 MeV source neutrons from the relatively few > 3 MeV fission neutrons signature with a good detection efficiency. Hydrogenous liquid scintillators (“LS”) with good pulse shape discrimination (PSD) capabilities are used to directly detect the high energy fission neutrons by discriminating them from the lower energy (d,D) source neutrons or the low energy (γ ,n) neutrons generated by the X-ray source used to stimulate fission. The energy discrimination process though considerably reduces the effective detection efficiency of the LS.

An altogether different detector type, called Threshold Activation Detector (TAD) (Gozani et al., 2011b), is entirely insensitive to events during the neutron or X-ray source pulses (or “flashes”). Rather it is activated by the high energy fission neutrons rendering the scintillation material itself slightly radioactive, emitting beta (and some gamma) particles that are very efficiently detected milliseconds to seconds after the source pulse. This activation (with a few seconds life-time) is measured well after the fission event, where the most of the interfering background radiation does not exist anymore.

Delayed neutrons

This technique detects the presence of fissionable material through the detection of neutrons emitted by the fission products from a fraction of a second to several seconds after the fission event occurs.

This signature is very unique to the fission process (“high specificity”) and is relatively easy to detect, as the detection is done well after the fission process has occurred and the neutron or the X-ray source stimulating the fissions is shut off. Large area thermalized ^3He or other similar thermal neutron detectors are being used (see also Fig. 9). The delayed neutrons can be measured between pulses of a pulsed source (e.g., pulsed d-T ENG or linac) or after short irradiation time, when the source is off. The main drawback of the delayed neutrons is their low energy and especially their low intensity. Thus, it is characterized as a “low sensitivity” signal.

Time correlation/multiplicity techniques

Time correlation techniques include a family of techniques based on the high multiplicity of the prompt particles (0–10 prompt neutrons, with an average of 3 and/or 0–20 prompt gamma rays, with an average of 7) emitted during the fission process. The multiplicity is measured by detecting prompt and/or delayed coincidences (depending on type of detector employed) between detectors. The overall fission multiplicity detection efficiency is inherently low because it is the product of the efficiencies of the individual detectors contributing to the coincidence detection (e.g., the single detector efficiency to the power of the multiplicity level sought). These techniques have been used in applications for relatively small objects, which can be practically enveloped with efficient detectors (Verbeke et al., 2007; Gozani, 1976, 1981; Boldeman and Hines, 1985; Hausladen et al., 2009).

Pulsed fast neutron activation (PFNA)

Pulsed Fast Neutron Analysis (PFNA) (Brown and Gozani, 1995; Rynes et al., 1999; Hellborg, 2005; Gozani and Strellis, 2007) is a technique that uses a collimated pulsed beam of fast neutrons (typical to 8 MeV) to excite the nuclei of common elements in explosive and other threats (C, N, O, and others) (Stevenson, 2006). Direct imaging of the elemental contents of the material is accomplished by using time-of-flight analysis to identify the position of the interactions and gamma-ray spectroscopy to identify the elemental gamma-rays. From the ratios and absolute measurements of elemental abundances, the identification of the material can be deduced. Even a small volume of explosives can be detected as they are characterized by a narrow range of (C, N, O) elemental ratios.

While PFNA might be the ultimate and most versatile cargo threat inspection system, it is considered the most expensive and complex. It requires intense nanosecond pulses of deuterons at 4–6 MeV to impinge on a deuterium gas target producing pulses of monoenergetic neutrons. A unique high-speed data acquisition system digitizes and analyzes the time-energy data in real time. A wide range of threats can be detected and located within the inspected volume (be it marine shipping container, air cargo containers, etc.). Fissionable materials can be detected and located, like the other threats, by the TOF of the monoenergetic source neutrons (typical 8 MeV) to the point of interaction plus the very short flight time of the prompt fission gamma rays.

The PFNA requires a relatively large accelerator (e.g., Van de Graaff) capable of intense nanosecond wide pulses with a MHz repetition rate, the ability of beam line and target to raster-scan a container in the vertically direction, a large array of efficient gamma detectors (such as NaI) and all associated electronics, and very fast data processing.

Associated particle technique (API) (Beyerle et al., 1990; Pino et al., 2018)

The API technique is similar to other techniques utilizing a neutron generator neutron source; however, it adds an alpha particle detector to measure the associated particle emitted simultaneously and 180 degrees from the neutron in the neutron producing nuclear reaction. For the d-T source, this is an alpha particle. For the d-D source, it is a He-3 particle. The direction of the neutron is determined by measuring the location of the detected associated particle. TOF is used to get location of the nuclear reaction. The useable intensity of the neutron source with this technique is inherently limited by the alpha detectors time resolution and cross talk between them. The fission signal that can be detected is the fission multiplicity beset by the same low efficiency mentioned in the Time Correlation techniques above.

Cargo activation

It is a well understood and expected that neutron interactions can create isotopes that are radioactive and create ionizing radiation as a result. This phenomenon is called activation. Neutrons (thermal to 14 MeV in energy) can activate cargo material and potentially impact the utility of the inspected cargo.

Extensive cargo activation studies have been conducted over the years and have shown that even with a strong neutron source ($> 10^{11}$ n/s of 8 MeV neutrons employed in PFNA) and expected scanning speeds there is no significant activation that will prevent consuming inspected food (including medications) or create external radiation hazards of any significance.

High energy (< 10 MeV) X-ray based inspection systems induced very little activation products, these being mostly created from secondary (γ, n) neutrons.

Photofission-based techniques (Stevenson et al., 2011; King et al., 2011a; Danagoulian et al., 2010)

As described briefly earlier in this chapter, photofission is a nuclear reaction whereby a high-energy photon induces the fission process in an element. The probability that a photon initiates a fission event is defined by the cross section. The cross section for photofission is energy-dependent, ranging from about 0.001 b at 6 MeV to about 0.1 b at 10 MeV. To put this into perspective, at the higher photon energies the cross section for U-235 is about one order of magnitude smaller than for fission spectrum neutrons and 3–4 orders of magnitude smaller than for thermal neutrons. Despite this deficiency, for practical applications, photofission does have an advantage over neutron-based active interrogation techniques. For what it lacks in available cross section, it gains in radiation intensity. Due mainly to other industrial uses (e.g., medicine, non-destructive testing), X-ray sources are well designed and tested across a wide energy range from tens of kV to tens of MV. The most widely-used X-ray source for security applications capable of screening cargo is the electron linear accelerators (linac) with electron energies at or below 10 MeV (currently limited by regulations). Commercial 9-MV linac X-ray sources can produce a total X-ray intensity of 10^{15} X-rays/s/100 micro-amps. Compared to commercial 14 MeV neutron sources, this is 5–7 orders of magnitude higher. Not only do these devices provide excellent sources of strong X-ray beams for radiography that are highly penetrating into dense cargos, they provide a radiation source capable of initiating fission via photofission process. Systems utilizing a high-energy linac source and radiography detectors are commonly deployed today for cargo screening in trucks, sea containers, and rail cargo.

A relatively straightforward method to add nuclear material detection to a standard high-energy radiography system would be to add a subsystem capable of measuring the photofission signatures.

Several techniques can be used for nuclear material detection through photofission using commercial linac X-ray sources as outlined in **Table 7**. Taking the first row, one could employ large plastic or liquid scintillators (Eljen, 2020) (or inorganic scintillators like NaI (Saint-Gobain, 2020)) to detect the total number, energy, and detection time of photons emitted after passing through the linac X-ray beam. The majority of delayed gamma-rays emitted after photofission are emitted 10s to 100 s of seconds after fission. This characteristic allows the detector subsystem to be separated in time from the linac X-ray source so that the emitted delayed gamma-rays can be measured in a reduced radiation background field. On average, about six delayed gamma-rays are emitted per fission, so the signature is strong. This method is specific to fissionable and fissile materials.

Similarly, following the second row, one could employ large moderated thermal neutron detectors (e.g., He-3 detectors) to detect the delayed neutrons from the photofission process. To reduce the radiation background from neutrons and electronic noise caused by the X-ray flux, the detectors would need to be sufficiently well shielded from the linac. A majority of the delayed neutrons emitted after U-235 photofission are emitted on the seconds to tens of seconds times scale. On average, only 0.012 delayed neutrons are emitted per fission. The signature is considered very weak, but very specific to fissionable and fissile material.

Alternatively, following the third row, one could deploy a detector that can differentiate between the highly ubiquitous photons and the fission signature neutrons. One can use a technique called pulse shape discrimination (PSD) (Zaitseva et al., 2012) with liquid scintillator detectors and solid organic scintillators to separate photons from neutrons. PSD works on the principle that neutrons and photons interact with protons and electrons, respectively, in the detector material, causing different time decay behavior in the detector's scintillation light. Another detection method for prompt neutrons is using a threshold activation detector (TAD). A TAD detects neutrons above a specific energy by measuring the beta activation induced by the neutron in the detector material itself (Gozani et al., 2011b). These detectors also need to be well shielded from source and scattered photons and neutrons. This technique is highly specific and has a good sensitivity for fissionable material.

In addition to the more straightforward methods outlined above, a linac X-ray source can be converted to a dual species neutron/photon source through the photoneutron reaction (γ, n) (King et al., 2011b; Gozani et al., 2010, 2011a). Practically, this technique requires the installation of a neutron converter near the X-ray target using a material with a photoneutron reaction threshold energy below the X-ray source energy. A likely candidate is heavy water that contains deuterium (^2H) or beryllium. When both neutrons and photons are present for active interrogation, one can utilize both photofission and neutron fission to create fission signatures. The additional benefit of a dual species source is that they are complementary in terms of cargo attenuation. Where photons have difficulties in penetrating metals, neutrons do not. Where neutrons have challenges in hydrogenous materials, photons do not. Thus, most cargo types can be penetrated by at least one or the other.

One challenge with photofission-based systems is the relatively strong photoneutron production by the (γ, n) reactions (an energetic photon ejecting a neutron from the nucleus it hits) with material around the X-ray source (e.g., converter, shielding and collimators) and in the surrounding environment (e.g., cargo and the air). Material containing isotopes with lower (γ, n) thresholds than the end point energy of the X-ray source (such as deuterium, which is always present in natural hydrogen), cause undesirable radiation background for measuring the fission signatures. The most important (γ, n) thresholds relevant for a 9 MV linac X-ray source are listed in **Table 8** for structural materials and key cargo isotopes and in **Table 9** for the commonly-employed linac converter and shielding materials.

The photoneutron intensity rapidly increases, along with the neutron energy, as the end point X-ray energy increases beyond the 8–9 MeV range. These neutrons, especially those with higher energy, constitute a significant background for the prompt neutron detectors. For deploying this technique to the field, a significant reduction of this background is highly desirable by properly considering the electron/X-ray converter, structural material, collimation, shielding and its system design. Linacs capable of operating with wider pulse width (commercial linacs operate with pulse width of $< 1 \mu\text{s}$), and with a significantly lower (γ, n) neutron background, are being currently developed (Tantawi, 2015; Condrón et al., 2013).

Table 7 Methods and signature for detecting fissile and fissionable material through photofission.

Technique	X-ray source/electron energy (MeV)	Signature	Detector configuration	Specificity/sensitivity (applicable to)
Photofission Delayed Gamma Detection	Linac, CW (or high DF)/ ≤ 10 MeV	Measure gross delayed γ rays (amplitude and time)	NaI, organic scintillators (PS, LS)	Medium-high/high (fissionable/fissile)
Photofission Delayed Neutron Detection	Linac, CW (high DF)/ ≤ 15 MeV	Measure delayed neutrons (amplitude and time)	Moderated ^3He or similar detectors	Very high/very low (fissionable/fissile)
Photofission Prompt Fast Neutron Detection (PFNP)	Linac, CW/ ≤ 9 MeV	Measure prompt neutrons above an Energy threshold	Well shielded LS (+PSD), TAD	High/medium high (fissionable)
Differential Die Away	linac with (γ, n) converter/ ≥ 6 MeV	Measure prompt neutrons by time and delayed neutrons (secondarily)	Moderated n det. (^3He or similar) with $\tau < 50 \mu\text{s}$	very high/ medium-high (fissile only)
Nuclear Resonance Fluorescence (NRF)	Variable energy intense CW electron accelerator (Rhodotron)	Resonant isotopic gamma lines	Large array of well collimated Ge detectors	very high/very low (fissionable/fissile + other elements)

Table 8 Photoneutron production threshold in cargo materials, relevant for 9 MeV X-rays.

<i>Isotope</i>	<i>Natural abundance (%)</i>	<i>(γ, n) threshold (MeV)</i>	<i>Where present</i>
H2	0.015	2.225	Cargo

Th232	100	6.44	Fissionable
Pu239	100	5.646	SNM

Photofission is a promising, albeit challenging, method for expanding the capability of currently deployed systems to detect nuclear material. The method does involve adding additional radiation detectors to measure the neutron or gamma-ray signatures from fission. Also, supporting tools like software and detection algorithms will require modification. However, the underlying methods for inspection and the X-ray source technology in many cases would not require modifications, except preferentially utilizing sources at the higher range of energy. For these reasons, photofission may be the most plausible method to deploy to real operational environments where nuclear material detection is considered a priority. A couple prototype systems utilizing photofission have been developed and have shown very good performance across a range of cargoes and nuclear materials employing the delayed gamma-ray signature. One system (Stevenson et al., 2011) utilizing a commercial 9-MV linac and the photofission delayed gamma-ray and prompt neutron detection methods is schematically shown in Fig. 12. This figure shows an X-ray radiography system mounted on a gantry that travels on rails to scan ISO 40-ft containers. Fission detectors (in blue) in the form of large plastic scintillators and TADs were mounted to the radiography detector array to measure the delayed gamma-rays and prompt neutrons from fission. Another successful manifestation of photofission-based inspection is the PNFP (Danagouliau et al., 2010), that is based on a powerful CW Rhodotron (JME, 2020) circular electron accelerator and multiple well shielded LS with PSD.

Nuclear resonance fluorescence (Bertozzi and Ledoux, 2005; Bertozzi et al., 2007)

NRF is not a photofission-based technique but it uses the ability of nuclei, (e.g. ^{14}N) to resonantly scatter/absorb gamma rays of specific and precisely defined energy (^{14}N : 9.17 MeV). For fissionable material detection, the resonantly scattered gamma rays are measured by collimated high resolution detectors (such as high purity germanium). The gamma rays originate from the different nuclear levels of fissionable isotope present in a voxel. The 3D voxels are defined by the volumetric intersection of the collimated X-ray beam and the subtended solid angle of collimated germanium gamma ray detectors. The gamma ray energies detected are very specific to each isotope. Thus, NRF is characterized as a technique with very high specificity. However, the technique has very low sensitivity because the number of photons that can be resonantly scattered is small even in an intense X-ray beam, and the overall germanium detector efficiency is very low due to the small solid angle the voxel subtends at the detector surface. Additionally, the specific gamma rays of the fissionable material are relatively low, 2–5 MeV making them more vulnerable to attenuation in the cargo material.

Fig. 12 A rendering of a photofission based active interrogation system that integrated a high-energy X-ray radiography system with fission signature detectors.

Conclusions

Active interrogation technologies employing, as appropriate, neutrons or high energy X-rays fill an important gap to detect nuclear and other threats. They can be combined with the existing technologies or stand alone. The research and development efforts over the last few decades clearly show that reliable active non-intrusive inspection of large objects (e.g., trucks, marine shipping containers, air cargo containers and smaller objects laden with commercial cargo) for nuclear material is an emerging technology. On-going research and development into electron linacs, detector materials, signal processing methods, and detection algorithms further increase the possibility of field deployment of these vital technologies as acquisition and operational costs are reduced.

Introduction: Uses of high activity sources and their benefits

Applications of radioisotopes have come a long way since their first practical use over a century ago. Today hundreds of radioisotopes, both natural and man-made, are routinely employed in medical, industrial, and research fields. The development and use of sealed radioactive sources have played a significant role in improving our quality of life as it touches almost every aspect of the modern society.

One of the most common applications of radioactive sources is radiotherapy (RT)—a widely used form of cancer treatment (Baskar et al., 2012). Radiation, used alone or in combination with surgery or chemotherapy, effectively destroys cancerous cells. External radiotherapy, also known as teletherapy, is provided by an external radiation source, usually cobalt-60, which emits 1.1 and 1.3 MeV gamma rays. Brachytherapy, or internal radiotherapy, places radioactive sources inside the patient. This technique

has the advantage of using a highly localized dose of radiation and significantly decreases the risk of radiation-induced second malignancies. Radioactive implants are inserted for hours, days, or, in some cases, even permanently. Currently, brachytherapy is predominantly used for localized tumours, such as cancers of the prostate, cervix, and endometrium. Mostly alpha- or beta-emitting radionuclides are used for brachytherapy due to their short penetration into biological tissues and high linear energy transfer. Among them are iodine-131, iridium-192, palladium-103, cesium-131, and ruthenium-106.

Another medical application of high activity sources is irradiation of blood before it is given to at-risk patients in blood transfusions. The irradiation is aimed at preventing transfusion associated graft-versus-host disease (TA-GVHD), a rare but nearly always fatal complication, in which transfused white blood cells attack the recipient's tissue (Moroff and Lunab, 1997). This process is commonly done using cesium-137 irradiators, and hundreds of them can be found worldwide. As will be discussed later, currently these sources are being replaced by non-radioisotopic irradiators in many countries.

Ionizing radiation is also used to sterilize healthcare products, including medical devices and pharmaceuticals (https://www-pub.iaea.org/MTCD/publications/PDF/Pub1313_web.pdf). Many single-use medical devices are supplied to the user as sterile products. Gamma irradiation, unlike other sterilization techniques, can penetrate products while sealed in their final packaging, which simplifies the manufacturing and distribution process. Implantable devices (orthopaedics, stents, etc.) as well as tissue-based devices coming from human donors, are also commonly sterilized with cobalt-60 to increase patient safety. Given the huge volume of devices which need to be sterilized, this processing is typically done in large commercial gamma facilities containing MCi (tens of PBq) quantities of cobalt-60.

High activity sources are also used for food safety and preservation and phytosanitary applications (<https://www-pub.iaea.org/MTCD/Publications/PDF/trs481web-98290059.pdf>). In the current global economy food is often consumed far from where it was produced. To extend its shelf-life during transport and storage, it needs to be preserved, which can be done by a variety of processes. In addition, transported produce needs to be free of pests that could disrupt the environment or agricultural regions where it is received. Ionizing radiation destroys pathogenic organisms such as parasites, bacteria, and viruses, and sterilizes insect pests. In many countries, food irradiation with cobalt-60 is routinely used to prevent sprouting or rotting, to delay ripening, and to reduce the risk of foodborne illness. Sterile Insect Technique (SIT) is another common application of gamma sources. *This insect* control method involves radiation sterilization of target *pests*, followed by the systematic area-wide release of the *sterile* males to mate with wild females without producing offspring. SIT has proved to be successful by eradicating several insect pests in various regions worldwide.

For almost a century radioactive sources have been used in industrial radiography to detect defects not visible from the outside (Committee on Radiation Source Use and Replacement, 2008). Cracks, flaws, or voids can be found by measuring the variation in the intensity of the radiation passing through an object. Examination of pipelines, boilers, parts and assemblies of vehicles and aircrafts, and other products has become widespread due to the convenience of compact and reliable sources of radiation. Radioactive sources are also used to monitor the thickness of items being formed, to monitor the density of material flowing through piping, or to measure the level of liquids in opaque containers (Monno, 2004). All of the above can be done by measuring the attenuation of radiation as it passes through matter.

Sealed radioactive sources are also routinely used in well-logging. Both gamma and neutron emitters are essential for evaluation of oil and gas formations. Formation density is typically measured by lowering Cs-137 source into a borehole and analyzing its scattered gamma rays. Porosity of formation is usually found with Am-Be neutron sources. As the formation is irradiated with neutrons, they scatter and thermalize. Low energy neutrons are easily absorbed by hydrogen, and therefore the neutron counting rate is inversely related to the amount of hydrogen (water and hydrocarbons) in the formation. The combination of neutron and gamma logs usually gives a rather accurate prediction of the feasibility of extracting oil or gas from a borehole (Pike and Duey, 2002).

Finally, high activity sources are widely used for R&D purposes. Thousands of research irradiators are installed worldwide and they are used intermittently for very diverse applications, including chemistry, biology, and material science. For example, small animals are irradiated to conduct preclinical studies in cancer research. Radiation-induced mutations help develop high yielding and disease resistant varieties of economically important plants and crops. New radiation resistant materials are tested in research irradiators.

From this brief review one can see the variety of applications of high activity sources in our daily life. The preferred radioisotopes for sterilization, blood irradiation, and food irradiation have historically been cobalt-60 and cesium-137. However, other isotopes are commonly used for brachytherapy and for non-destructive testing. Table 1 summarizes the properties of the most commonly used radioisotope sources.

Radioisotope life-cycle: From cradle to grave

Numerous applications of radioactive sources, some of which are described above, require reliable supplies of radioisotopes. There are several approaches to isotope production, but the two main instruments required to make radioisotopes are particle accelerators and nuclear reactors (Starovoitova, 2017). While many radioisotopes are produced in accelerators, this method is mostly suitable for short lived (hours to days) isotopes, commonly used in radiopharmaceutical science and nuclear medicine. Longer lived radioisotopes, used for sealed sources, typically require long (months to years) irradiations. Therefore, most radioisotopes for radioactive sources are produced in nuclear reactors—both research and power. Neutron capture is the most common

Table 1 Most commonly used radioisotopes for radioactive sources, their properties and applications.

<i>Application</i>	<i>Radioisotope</i>	<i>Half-life</i>	
Industrial irradiators	Cobalt-60	5.3 years	Used in metallic form, which oxidizes in air, but is not soluble in water
	Cesium-137	30.1 years	Used typically in form of cesium salts (typically chloride), which are highly soluble in water. Sometimes used in ceramic form for weak sources
Industrial radiography	Cobalt-60	5.3 years	See above
	Iridium-192	74 days	Iridium is a noble metal, not oxidized in air, not dissolved in water
	Selenium-75	120 days	Used in form of thermally stable metal-selenide compound (typically with vanadium)
Gauges	Cobalt-60	5.3 years	See above
	Cesium-137	30.1 years	See above
	Californium-252	2.6 years	Californium is a highly reactive actinide and typically used in form of alloys or cermets
	Krypton-85	10.7 years	Gas
	Americium-241	432 years	Americium metal is not chemically stable, thus usually used as oxide powder in a capsule
Well-logging	Cesium-137	30.1 years	See above
	Americium-251/Beryllium	432 years	Used in form of mixed oxide powder or pellets
Research	Cobalt-60	5.3 years	See above
	Cesium-137	30.1 years	See above
	Americium-251/Beryllium	432 years	See above
Teletherapy	Cobalt-60	5.3 years	See above
Brachytherapy	Cesium-131	9.7 days	Cesium containing core in a thin aluminum jacket inside a Teflon capsule
	Cobalt-60	5.3 years	See above
	Iridium-192	74 days	See above
	Iodine-125	60 days	Often used as absorbed into silver matrices
	Palladium-103	17 days	Palladium doped polystyrene in titanium capsules
Blood irradiators	Cobalt-60	5.3 years	See above
	Cesium-137	30.1 years	See above

reactor-based production method due to high reaction cross section. Examples of radioisotopes produced by neutron capture include cobalt-60 and iridium-192:

Irradiated pellets are transferred to a manufacturing facility, where sealed sources are produced under strict quality control and quality assurance systems, such as ISO9001. Manufacturing the finished sources usually requires shielded hot cells with remote manipulators and specialized equipment. The finished products are normally double-encapsulated, welded stainless steel sources, identified with a unique serial number.

Radioactive sources (defined as Class 7 material in the UN Model Regulations on Dangerous Goods) need to be transported several times during their life-time. Multiple modes of transport are used including roads, railroads, air, and waterways for consignments. Often, country borders are crossed. Special packaging or casks are required to contain the radioactive content and control the external radiation levels. All of the above entails the stakeholders to adhere to various directives, laws, and regulations. The International Atomic Energy Agency (IAEA) has published international regulations for the transport of radioactive material since 1961, with the latest released in 2012 (https://www-pub.iaea.org/MTCD/Publications/PDF/Pub1570_web.pdf). Many countries have adopted IAEA regulations into their national policies. Careful planning, effective communication and coordination is a must for safe and secure transport.

When the activity of the sources drops, they are no longer suitable for their intended purposes. Rarely, these sources still can be used for training or R&D at local universities and laboratories. However, most often, the sources are disposed of by being returned to the manufacturer or by storing them in specialized waste facilities. Unfortunately, many countries lack the appropriate disposal facilities. Therefore, management of radioactive wastes and the long-term safety and security of disused radioactive sources remains a concern at the international level.

Lost and stolen sources

Millions of radioactive sources have been produced worldwide, although the existing databases indicate a smaller number. For various reasons, a significant number of radioactive sources have become obsolete. At this stage, the sources are often not properly controlled and can be lost or stolen. Over the decades there have been a number of incidents and accidents. One of the most serious accidents, ranked as level 5 on the IAEA International Nuclear Event Scale (INES) (<https://www.iaea.org/publications/10508/ines-the-international-nuclear-and-radiological-event-scale-users-manual>), took place in 1983 in Goiania, Brazil.

A 51 TBq (1.4 kCi) cesium-137 source was stolen from an abandoned hospital building and sold to a local scrapyard. Shortly after, the capsule was broken and people were fascinated by the blue glow coming from cesium. Many family members and friends visited, and no one understood the nature nor the danger of the material even after people started feeling sick. Only days later radioactivity was detected, and a large-scale screening operation was initiated. By that time a large part of the city was contaminated as cesium was transferred by wind and rain. People were evacuated, houses were demolished, whole streets and squares decontaminated, and soil removed. Over 100,000 people were screened and more than 200 were found to be irradiated. Thousands got sick and four people died from radiation poisoning.

Another serious accident, INES level 4, took place in Myapuri, India, in 2010. Its story is similar to the one in Goiania: an abandoned cobalt-60 source from an old research irradiator was sold to a scrap yard. After immediate contact with the source, several people received a significant dose and one person died. Many other accidents and incidents involving abandoned radioactive sources, such as cobalt-60 and cesium-137, have transpired over the last several decades. Among them are events in Casablanca, Morocco; Mexico City, Mexico; Baku, Azerbaijan; Chiba, Japan; Los Angeles, USA; and many, many others (<http://www.irpa.net/irpa10/cdrom/00140.pdf>).

Often, during these accidents, people did not know what they were dealing with until they started feeling sick. However, there are several cases when radioactive material was stolen on purpose, with a clear malicious intent. For example, in 1999, six people attempted to steal cobalt-60 rods in the *Chechen Republic of Russian Federation*. After handling the rods, three of them died, and the other three were severely injured. It is possible that their intent was to use this radioactive material in their struggle against Russian federal troops, who at that time were re-establishing central government control over Chechnya. Moreover, many events have been reported when radioactive material was used in attempts, sometimes successful, to murder people (<http://www.johnstonsarchive.net/nuclear/radevents/LAUR073686.pdf>).

The IAEA Incident and Trafficking Database (ITDB), launched in 1993 and updated annually, contains information on voluntarily reported incidents involving radioactive materials (<https://www.iaea.org/sites/default/files/19/04/itdb-factsheet-2019.pdf>). While the database is confidential, the IAEA annually releases a summary without the details of individual accidents. Several hundred incidents are reported annually by participating countries and most of them involve industrial and medical radioactive sources. The majority of incidents are related to unauthorized disposal and shipment and the discovery of uncontrolled radioactive sources. Many cases involve detection of goods contaminated with radioactive material. The most common source of such contamination is feed metal, often obtained from the recycling industry. As the feed is melted down, it can become contaminated with undetected radioactive material such as cobalt-60. If the resulting contaminated metal is used for household goods, it could pose health problems to their consumers. Some incidents are related to missing or stolen material. Devices containing radioactive sources often look valuable to potential thieves. Most such devices use significant quantities of relatively long-lived isotopes such as cesium-137, cobalt-60, and iridium-192. Few incidents demonstrate intent to acquire or provide radioactive material for malicious use. Most of them are rather amateur or opportunistic in nature. However, several cases were reported to be better prepared and resourced.

Only some countries systematically report the incidents involving the loss of radioactive material to the IAEA ITDB. A more comprehensive database is annually prepared by the James Martin Center for Non-proliferation Studies (https://media.nti.org/documents/global_trafficking_2017.pdf) through exhaustive multi-language searches of media and government sources. According to their data, more than half of the incidents were at least partially caused by human error. Examples include material left unattended in the lab and lost, device not properly secured in a car, so it fell off, etc. About a quarter of incidents involve theft of radioactive material, and more than half of those took place when the material was in transit. Material was stolen both from the vehicles and with the vehicles. In most of the cases the vehicle was unattended at the time of theft and thieves were most likely unaware of what they had stolen. These results call for a stronger security culture in organizations that use, transport, and store radioactive materials.

Dirty bomb—Real danger

While the majority of incidents described above do not necessarily imply malicious use of radioactive sources, there have been attempts to buy and sell radioactive and nuclear material. While small quantities of cobalt or cesium cannot be used to make a nuclear bomb, they are capable of causing radiation poisoning and sickness. This makes high activity sources an attractive target for terrorists seeking to build a so-called “dirty” bomb. A *dirty bomb*, also known as a radiological dispersal device (RDD), combines radioactive material with a conventional explosive to spread it. A radiological weapon would not produce a nuclear explosion and would cause few (if any) immediate casualties. However, if detonated in a major city, an RDD could potentially contaminate a significant area and spread fear among population. Therefore, its *primary* destructive power would not be radiation, but *panic* and consequent financial losses. Analysis of the impact of a dirty bomb attack on the Port of Los Angeles and Long Beach predicts the extensive shutdown of the region’s operations and hundreds of billions of US dollars in losses (Rosoff and von Winterfeldt, 2007). Another study considers an RDD attack in the area of the New York Stock Exchange and estimates losses to reach \$1 trillion (Sudnik, 2011).

A dirty bomb has never been detonated. However this does not mean that it cannot or will not happen. Given the massive amount of existing radioactive sources, both used and disposed, many experts consider the eventual detonation of RDD to be highly likely. What can be done to reduce the risk and minimize the probability of such a frightening event? Obviously, more attention must be paid to the security of existing radioactive material. Numerous documents and guidelines exist to help. For example, IAEA’s

“Code of Conduct on the Safety and Security of Radioactive Sources” (<https://www.iaea.org/publications/7227/code-of-conduct-on-the-safety-and-security-of-radioactive-sources-guidance-on-the-import-and-export-of-radioactive-sources>) provides strategies for governments to establish the legal provisions necessary for the protection of high-activity sources. However, only two thirds of IAEA Member States endorsed the Code, and even fewer implemented all its recommendations. This means that many sources are still not safely and securely used, stored, transported, and disposed. In addition to taking proper care of the radioactive material already existing around us, can we minimize the number of sources? The answer is yes. Many benefits of radioactive sources without their risks can be provided through alternative technologies.

Alternative technologies

Many governments and international organizations, including the IAEA, are concerned about high activity source security and provide institutional support for the institutional support for the adoption and development of non-radioisotopic alternatives. The most common substitution for radioactive sources is X-ray tubes and electron accelerators, some of which can operate in e-beam mode and X-ray mode. The main advantages of these alternative technologies are their ability to be turned on and off for safety and their minimal security risks. These machines cannot produce residual radioactivity, and therefore do not result in radioactive waste. Historically, such accelerators were complex and rather expensive. However, lately, numerous models have been developed for various applications, and many of them are compact, versatile, and much more reliable.

One of the most widespread sources of X-rays is the X-ray tube—a simple tool, developed over a century ago, but still widely used in medicine, industry, and science. An X-ray tube consists of a cathode, which emits electrons. Accelerated by an electric field, the electrons bombard the metal anode. As the incident beam of electrons pass through the anode, they are primarily slowed down by the Coulomb field surrounding nuclei. The difference between the electron’s initial energy and its final energy is emitted in the form of photons, also known as bremsstrahlung radiation. The bremsstrahlung energy spectrum of photons is continuous, ranging from nearly zero up to the applied voltage. X-ray tubes are simple, compact, and robust. However, their energy output is limited to a few hundred keV, which is less than the energy of gamma rays emitted by cesium-137 and cobalt-60.

Electron accelerators also use electron guns (cathodes) to produce a collimated electron beam, which is accelerated with either DC voltage or RF cavities. Large machines can accelerate electrons to hundreds of GeV, however for industrial purposes, the energy of the electrons should not exceed 10 MeV and should be even less for some applications. This energy can be achieved with rather compact units. High energy electrons can be used “as is,” which is suitable for irradiation of low density or thin products. Alternatively, they can be converted into X-rays using a converter—a thin plate of high Z material, such as tungsten or tantalum. The resulting X-rays are highly penetrable, but the efficiency of the conversion process does not exceed more than a few percent. Fig. 1 depicts the bremsstrahlung radiation process (left) and the distribution of photon energies simulated for a 9-MeV electron beam impinging upon tungsten converter (right). It also shows lines corresponding to the energy of gammas emitted by cesium-137 (661 keV) and cobalt-60 (1.1 and 1.3 MeV) for comparison. The mean energy of bremsstrahlung photons can be roughly estimated as one third of the electron beam energy. Thus, a 9 MeV electron beam results in mean photon energy to be about 3, and a 4 MeV electron beam will be “gamma-energy-equivalent” to the cobalt-60 source.

Accelerators and X-ray tubes can potentially replace radioisotopic sources in many areas listed in Table 1. However, they have their own drawbacks, among them relative complexity of the technology, stable power supply requirements, and large unit size in some cases. As a result, non-radioisotopic technologies are more applicable to some uses of gamma sources than others. In the

Fig. 1 (Left) Bremsstrahlung radiation process and (Right) bremsstrahlung spectra simulated with MCNPX for 9-MeV beams hitting a thick tungsten converter. Energies of gamma rays emitted by Cs-137 (blue) and Co-60 (red) are also shown for comparison.

following sections, several applications of sources and discuss advantages and disadvantages of their non-radioisotopic alternatives will be addressed.

Blood irradiators

To prevent TA-GVHD, a potentially fatal complication of blood transfusion—especially for immunocompromised patients—blood needs to receive 15–50 Gy of dose. Thousands of cesium blood irradiators were installed worldwide and have been used routinely for this purpose. However, the situation changed about a decade ago when several programs were initiated to motivate the users of cesium sources to switch to alternative technologies. Licensees who choose to replace their cesium irradiators with non-radioisotopic technologies are eligible to various incentives, including financial ones. As a result, in some countries, such as Norway, France, and Denmark, all cesium blood irradiators were replaced. In others, such as Japan or USA, the conversion is still ongoing, rather successfully. The US DOE NNSA ORS initiated the Cesium Irradiation Replacement Project and more than 100 cesium irradiators have already been phased out in several locations, including New York City and the University of California system. More replacements are planned for the next few years in the US.

Several low-energy self-shielded X-ray machines are currently available to replace cesium blood irradiators. These units are compact and self-shielded so they can easily be installed in a regular room in a hospital and are easy to use. While the energy of the X-rays they generate is significantly lower than 661 keV, their high current results in high dose rate, typically several Gy/min. This allows irradiating several blood units in just a few minutes. The main disadvantage of X-ray irradiators is their high maintenance cost.

The licensees interested in replacement consider different factors (see Table 2), but the main two are infrastructure requirements and costs, both capital and operational. Developing countries present a unique set of challenges due to their limited financial resources and lack of advanced infrastructure. In this situation cesium irradiators, which are easy to operate, might look very attractive over the short term. However, rather than merely accepting the “simpler,” but potentially threatening technology, the developing world should consider investments in personnel training and development of advanced infrastructure, and the costs should be mitigated through international support. The recent world-wide effort in replacing cesium irradiators with X-ray units is a positive step and a great example of successful introduction of alternative technologies. This work should continue to expand to effectively reduce the risk of terrorism.

R&D irradiators

Unlike blood irradiation, which is well defined in terms of required dose and irradiated product, R&D applications of gamma sources are extremely diverse. R&D gamma irradiators are used in biology, geology, material studies, and other areas of science and technology. Dose requirements differ greatly: from 2 to 10 Gy for small animal studies to 100 kGy for investigation of radiation-induced polymer degradation. Due to its long half-life, cesium-137 is widely used for R&D purposes, with hundreds of cesium research irradiators (1–100 kCi each) installed worldwide. Many research institutes, universities, and government laboratories consider and even already have begun the conversion from cesium to X-ray devices or electron accelerators. However, this process has a number of challenges. Existing low energy X-ray machines described above might be a good substitute for cesium blood irradiators; however, not all the models can provide the high penetration depth and good dose uniformity ratio (DUR) needed for some uses of research irradiators. To fully match the dose penetration of cesium research irradiators, an accelerator with at least 2.5 MeV electron beam energy is often required. A new generation of accelerators, for example 3–7 MeV machines, can potentially replace cesium sources for diverse R&D work.

Cobalt-60 has a significantly shorter half-life compared to cesium and, therefore, is less common for R&D applications. Nevertheless, about 500 self-shielded cobalt-60 installations (with up to 100 kCi of cobalt) are estimated to be present worldwide in research institutes, universities, and government laboratories. Uses of cobalt-60 research irradiators are as diverse as uses of cesium-137 research irradiators. Since cobalt has twice as high gamma ray energy, it is often used for studies that need even better penetration and DUR than provided by cesium units. Note that 3–7 MeV, 0.1–0.3 mA accelerators, which could replace cesium and

Table 2 Advantages and disadvantages of cesium blood irradiators and X-ray systems.

	<i>Cesium irradiators</i>	<i>X-ray systems</i>
Advantages	• Simple and reliable technology • No advanced infrastructure is required	• Long term cost saving • Safety and security are less of an issue • Can be turned on and off
Disadvantages	• Uncertainty in future cesium costs • Maintenance of expensive license, surveillance systems and security procedures • Costly disposal of cesium	• High initial cost to replace the unit • Requires stable power supply • Requires highly trained personnel • Lower reliability compared to cesium unit; need to have a backup system

cobalt research irradiators, will require extensive shielding and will most likely not fit into the original lab space. Lab expansion or construction of a new facility will increase the costs of the replacement project. On the other hand, accelerators with variable energy, dose rate, penetration depth, and field profile, will open new opportunities for scientists.

Larger (few hundred kCi) cobalt-60 research irradiators are even less common than self-shielded cobalt units. However, a few dozen such facilities are installed worldwide. A typical facility consists of a concrete bunker with a source pool (or source rack) in the middle. Products to irradiate are usually placed around the source, sometimes on turntables. This setup can accommodate larger volumes of samples compared to self-shielded units. It might be possible to retrofit such a facility by replacing the cobalt-60 source with a 3–10 MeV, 2–10 mA accelerator. In this case, water needs to be removed (in case of wet source), and the accelerator needs to be installed in the pit with the electron beam going upwards. Bending magnets can be used to bend the electron beam so that it's horizontal. Adding a bremsstrahlung converter and rastering magnets will result in a bremsstrahlung photon beam on the conveyor. In many cases it might not be possible to retrofit the existing facility, and a new facility needs to be built.

Replacement of research irradiators with alternative technologies has begun, but it is a challenging process. Accelerators to replace cesium and cobalt R&D irradiators already exist. However the current state of technology would not meet the expectations of the market in terms of price, complexity, reliability, and maintenance. Further development of the technology and transition should be supported by governmental and international organizations.

Teletherapy

The major modality of curative or palliative treatment of cancer, which continues to be one of the leading causes of mortality worldwide, is radiotherapy (RT). The first RT units were developed in the 1950s and contained cobalt-60 as a source of gamma radiation. In a typical design, the cobalt source is just stored in a shielded head where it can be moved pneumatically. During the treatment the source is moved next to an opening through which the gamma beam exits. After the treatment is over, the source is returned to the shielded position. Collimators, flatteners, jaws, and trimmer bars are used to adjust the radiation field as needed. A typical teletherapy machine contains a capsule with 5–10 kCi of cobalt and provides few Gy/min dose rate to a patient. The sources are usually replaced every 5–6 years when the dose rate becomes “too low.” However, financial considerations often result in longer usage.

Due to a relatively simple design and operating requirements, this invention provided a tremendous boost in cancer treatment and today more than 10,000 cobalt units are operational over the world (<https://dirac.iaea.org/>). However, at about the same time the first cobalt units appeared, development of medical linacs also began. Various types of linacs are currently available for clinical use. Some provide only X-rays, while others provide both X-rays and electrons at megavoltage energies. Modern machines offer dual photon energy and multiple electron energies anywhere in the 6–25 MeV range, photon beam intensity modulation with multi-leaf collimators, and full dynamic conformal dose delivery with intensity modulated beams.

The complexity of modern multimodal linacs makes it possible to perform conformal treatments of the tumor, which could not be done with cobalt units. It is no wonder that increasingly sophisticated generations of linacs replaced many cobalt machines and became the most commonly used tool in modern RT. Despite the clear technological advantages of linacs, cobalt units still play an important role in RT, especially in the developing world, which has higher populations and fewer financial resources. Replacement of cobalt machines in developing countries is difficult, due to their considerably lower capital, installation and maintenance costs, simplicity of design, and ease of operation. While linacs continue to become more reliable and affordable, cobalt units will likely play an important role in cancer therapy for the foreseeable future.

Industrial irradiators

Industrial cobalt-60 irradiators are primarily used for food or phytosanitary applications and medical device sterilization. They operate in either continuous or, less commonly, in a large batch mode, and products to be irradiated come in pallets or tote boxes. Food irradiation requires relatively low doses: less than 1 kGy to inhibit the growth of sprout, slow the ripening process, and kill insects and larvae that can be found in grains, fruits, and vegetables after harvesting; and up to 10 kGy to destroy pathogens in meat and fish, control molds and extend shelf life in fresh products. Therefore, food irradiation processing typically relies on small (~1 MCi) industrial irradiators, which can rapidly provide 1–10 kGy doses. Large industrial irradiators (greater than 1 MCi) are almost exclusively used for medical device sterilization as they can deliver high doses required for medical products (25–50 kGy) at high speed. If needed, they can also be used for food or phytosanitary applications with a split source rack.

Gamma irradiation is an established and simple technology with about 500 MCi of cobalt-60 installed at about 200 facilities (<http://iiaglobal.com/wp-content/uploads/2018/01/White-Paper-Comparison-Gamma-Eb-Xray-and-EO-for-Sterilisation.pdf>). Many producers of medical products have been using it for decades. Moreover, many new medical products are designed and developed with gamma sterilization modality in mind and it will be costly to change it. However, raising security concerns, recent perturbations in cobalt supply, and sharp increases in its cost have made many users consider alternative technologies. E-beam technology has gained popularity, but it is not suitable for many products. In addition, it requires much more complex machinery and maintenance, which can result in prolonged shutdowns. It also requires a reliable supply of electricity, which can be an issue in some countries. However, it is very cost efficient and provides very high product throughput. X-ray technology is similar to e-beam in requirements as it uses the same accelerators. However, during the electron-to-photon conversion a significant fraction of energy is lost and the economic viability is not as great as in the case of an e-beam. On the other hand, this method can be used for a much wider portfolio

Table 3 Gamma, e-beam, and X-ray irradiation and their advantages and disadvantages.

	<i>Gamma</i>	<i>E-beam</i>	<i>X-ray</i>
Technology	• Relatively simple and reliable • Good uptime	• Complex technology • Fair uptime • Requires more personnel	• Complex technology • Fair uptime • Requires more personnel
Products	• Good penetration, can treat “dense” products	• Poor penetration, limited to low density and thin materials	• Good penetration, can treat “dense” products
Security	• Good safety record • Cannot be turned off • Depleted sources are an issue	• Good safety record • Can be turned on and off • Does not produce radioactive material	• Good safety record • Can be turned on and off • Does not produce radioactive material
Maintenance	• Cobalt needs to be replaced regularly • Limited suppliers and uncertainty of future availability of cobalt • High price of cobalt	• Requires stable power supply and backup systems for critical utilities • Maintenance service contract usually required	• Requires stable power supply and backup systems for critical utilities • Maintenance service contract usually required
Costs	• High capital costs • High costs of cobalt	• High capital costs	• High capital costs
Public acceptance	• Low	• No concerns	• No concerns
User acceptance	• Good	• Good	• Low, as technology is relatively unknown

of products. Several facilities now equip their accelerators with removable X-ray converters so that they can be used in both modes, e-beam and X-ray, as needed. Nevertheless, this method remains relatively unknown to medical product producers. The three main irradiation modes described above, and their advantages and disadvantages are summarized in [Table 3](#).

Industrial irradiation is one of the most challenging domains for alternative technologies. To provide high dose rates required for high product throughput, one would need reliable accelerators delivering both high energy (as close to 10 MeV as local regulations allow) and high power (tens of kW) beams. Only a handful of companies in the world produce such machines, and they are still complex and expensive. To replace industrial cobalt irradiators, more than one accelerator should be installed in each facility—both to provide the throughput and to offer backup in case of maintenance or shutdown.

Conclusions

It is nearly impossible to imagine our life without radioactive sources and it is difficult to overestimate their importance. However, several hundred incidents involving sources are reported annually, and this might be just the tip of the iceberg. To make it worse, in some cases, it was obvious that the material was planned to be used maliciously. After the terrorist attacks on the United States on September 11, 2001, concerns about the safety and security of radioactive sources grew, including the fears of a “dirty bomb.” To minimize the threats of misuse of sources it is essential to improve the security culture, and to minimize the amount of radioactive material around us by introducing alternative technologies.

For many applications, alternative, non-radioisotopic technologies have been around for a while. However, due to their complexity and high costs, these methods were often overlooked. Raising safety and security concerns increased interest to these techniques. For some applications, such as blood irradiation, the transition to X-ray technology is very successful. For other applications, such as industrial sterilization of medical devices, the progress is not as great due to the lack of powerful, reliable, and inexpensive accelerators.

Radiation sources are essential to securing our health, safety, and prosperity, and they should be replaced with caution, to make sure that the alternative technologies are viable, practical, and preserve the benefits of the sources. Potential risks should be evaluated as well as potential benefits and all the trade-offs should be carefully considered. There is no doubt that alternative technologies will become more and more widespread. However, this process will take time and will require strong support from governmental organizations and international agencies. Market, regulatory, and licensing incentives should facilitate the introduction of alternative technologies and reduce the attractiveness of radioactive sources. This work should continue to expand worldwide to effectively reduce the threat of radiological terrorism.

Acknowledgments

It is a professional privilege for me to have been chosen by the Editor of the Volume, Dr. Alan Waltar, to handle the important task of discussing the risks of radiation sources and alternative technologies. I would like to acknowledge with much appreciation the excellent support received from my colleagues, especially Ms. Kristin Hirsh and Mr. Lance Garrison from the US DOE NNSA. It is envisaged that the present volume will be found valuable by not only scientists and engineers, but also by various stakeholders in countries across the world and in international agencies.

Glossary (IAEA, 2015a,b)

Categorization or identification (IAEA, 2014) A process performed to address the threat posed by a specific incident, with the goal of identifying the risk to the safety of first responders, law enforcement personnel and the public and determining if there is criminal activity or a threat to national security.

Chain of custody The procedures and documents that account for the integrity of physical evidence by tracking its handling and storage from its point of collection to its final disposition.

Characterization Determination of the nature of the radioactive material and associated evidence.

Improvised nuclear device A device incorporating fissile materials designed to produce a fission chain reaction. Such devices may be fabricated in a completely improvised manner or may be an improvised modification to a nuclear weapon.

National nuclear forensics library An administratively organized collection of information on nuclear and other radioactive material produced, used or stored within a State.

Nuclear forensic interpretation The process of correlating sample characteristics with existing information on types of material, origins and methods of production of nuclear and other radioactive material, or with previous cases involving similar material.

Nuclear forensics Nuclear forensics is the examination of nuclear or other radioactive material, or of evidence that is contaminated with radionuclides, in the context of legal proceedings under international or national law related to nuclear security.

Nuclear security event An event that has potential or actual implications for nuclear security that must be addressed.

Nuclear security The prevention of, detection of, and response to, criminal or intentional unauthorized acts involving or directed at nuclear material, other radioactive material, associated facilities, or associated activities.

Radiation exposure device A device with radioactive material designed to intentionally expose members of the public to radiation.

Radiological crime scene A crime scene at which a criminal act or intentional unauthorized act involving nuclear or other radioactive material has taken place or is suspected.

Radiological dispersal device A device to spread radioactive material using conventional explosives or other means.

System for nuclear material accounting and control An integrated set of measures designed to provide information on, control of and assurance of the presence of nuclear material, including those systems necessary to establish and track nuclear material inventories, control access to and detect loss or diversion of nuclear material, and ensure the integrity of those systems and measures.

The role and origins of nuclear forensics

The role of nuclear forensics in combating crime and terrorism

In 2005 the International Atomic Energy Agency (IAEA) officially defined the new discipline and the major part of its work, nuclear security, as the complex of laws, regulations, institutions, systems and measures aimed at the “prevention of, detection of, and response to, criminal or intentional unauthorized acts involving or directed at nuclear material, other radioactive material, associated facilities, or associated activities” (IAEA, 2005). Even though the official definition of nuclear security does not itself mention nuclear terrorism, the document that introduced it did connect nuclear security with “measures to protect against nuclear terrorism” (IAEA, 2005). A nuclear security event is an “event that has potential or actual implications for nuclear security that must be addressed” (IAEA, 2015b).

Nuclear terrorism was officially defined the same year with adoption of the 2005 International Convention for the Suppression of Acts of Nuclear Terrorism (ICSANT). This convention provides a strict legal definition of nuclear terrorism as a set of specific offences (listed in Article 2) that can be performed by non-state actors, and provides a framework for legal action. ICSANT does not cover actions of states, nor offences that were completely confined to the territory of one state and did not include anyone other than the nationals of that same state. Thus, nuclear security is understood as defence against nuclear terrorism within the framework of the international, UN-linked legal mechanisms and organizations. Nuclear security also works at the level of individual states to deal with nuclear security events, but those, even if the same in nature, would not qualify as acts of nuclear terrorism under ICSANT.

While the exact legal definition of nuclear terrorism is given in ICSANT, in practical terms it is understood as one (or more) of the following four actions by a non-state actor: (a) theft and/or use of a nuclear warhead obtained from a state; (b) theft of a nuclear material and making of an ‘improvised’ nuclear explosive device; (c) obtaining radioactive material and using it directly or making a “dirty bomb” or any other device designed to disperse radioactivity; (d) attacking a nuclear installation (Ferguson et al., 2005).

Nuclear forensics has been established well before nuclear security was defined as a field. (See section **Nuclear forensics and its origins** below.) The newest IAEA definition of nuclear forensics states: “Nuclear forensics is the examination of nuclear or other radioactive material, or of evidence that is contaminated with radionuclides, in the context of legal proceedings under international or national law related to nuclear security” (IAEA, 2015a,b). Nuclear forensic science (also referred to as nuclear forensics) is seen as a subdiscipline of a general forensic science dealing with nuclear or other radioactive materials within the framework of legal mechanisms pertinent to nuclear security. It is aimed at strengthening the nuclear security regime through two out of three mechanisms mentioned in the definition of nuclear security: (1) response (including an investigation of a nuclear security event and possibly determination of the material’s source, point of origin and route of transfer), (2) prevention of future cases by identification of suspect material origin or point of loss of control, and improvement of material’s control, accounting and physical protection there (IAEA, 2015a,b).

Nuclear forensics can be useful in at least three out of four nuclear terrorism scenarios described above: (a) theft and/or use of a nuclear warhead, (b) theft of nuclear material for the purpose of creating a nuclear explosive device, and (c) theft and/or other illicit use of radioactive materials or sources. Each of these scenarios has two subscenarios: before and after the actual terrorist act that would result in an explosion of some kind or possibly a dispersion of radioactive material by other means, including poisoning (McFee and Leikin, 2009). Table 1 mentions indicative or typical tasks of the nuclear forensic science in those scenarios.

Although there is some discussion concerning this general topic in the scientific literature, nuclear terrorism scenarios that involve an actual stolen nuclear weapon are considered less likely than those that involve an improvised nuclear explosive device. Those that involve dispersal of radioactive materials are considered the most likely of the three (Volders and Sauer, 2016).

Table 1 Potential tasks for nuclear forensic science aimed at prevention of or response to nuclear security events, including nuclear terrorism acts.

	<i>Nuclear security events, involving</i>		
	<i>A nuclear warhead</i>	<i>An improvised nuclear explosive device (IND) from illegally obtained nuclear material</i>	<i>Dispersal of radioactive material (including poisoning)</i>
Before the explosion or dispersion	Identification of origin and/or production date of fissile material in a warhead	Identification of origin and/or production date of fissile or other nuclear material found outside of regulatory control	Analysis of radioactive material to assist investigation (e.g. by determining the material's origin or age); or collection of "traditional" evidence from surfaces contaminated with radionuclides.
Post-explosion or dispersion	Analysis of particles and gases (from weapon debris) for understanding the design features of the exploded device and assisting attribution	Analysis of particles and gases (collected after the explosion) for understanding the design features of the exploded device and assisting attribution	Analysis of particles (from a radiological dispersal device) and/or human tissue, clothing and excretions; or collection of "traditional" evidence from surfaces contaminated with radionuclides.

Highlighted table cells represent areas where real incidents happened, and they are also the ones that are most often discussed in open literature on nuclear forensics and nuclear security.

Luckily, successful dispersals of radioactive materials with malicious purposes are rare and there has not as yet been a terrorist act that would involve a real nuclear explosive device. In order to prevent such instances from happening, a large amount of work has been done internationally to address a potential precursor to such events; namely, the existence of nuclear or other radioactive materials outside of regulatory control (MORC), and in particular, an illicit trafficking of such materials across national boundaries—a phenomenon known colloquially as nuclear smuggling. In its broadest sense, illicit trafficking refers to criminal or unauthorized acts involving MORC, such as their "import, export, possession, sale, delivery, movement, use, storage, disposal or transfer" (IAEA, 2007).

To summarize, nuclear forensics is most often seen as a nuclear security tool intended to aid criminal investigation of illicit trafficking or nuclear terrorism cases. One should keep in mind, however, that nuclear smuggling was happening (and nuclear forensics was used to investigate it) before nuclear security was formally defined as a discipline, and nuclear forensics techniques have also been used to investigate cases not pertinent to nuclear security.

Nuclear forensics and its origins

Before the 1990s, the issue of nuclear and other radioactive materials outside of regulatory control was not completely unknown. But the threat was low level, isolated and more relevant to the field of nuclear non-proliferation than nuclear security (Fedchenko, 2017). This changed in the early 1990s, following the disintegration of the Soviet Union.

By the time of its breaking up into independent states, the Soviet Union had by far the largest arsenal of nuclear weapons in the world (Norris and Kristensen, 2010). It is also estimated to have had the largest stockpile of highly-enriched uranium (HEU) and plutonium (Glaser and Mian, 2008). It is clear that vast quantities of nuclear and especially of other radioactive materials and radioactive sources, as well as nuclear facilities, have been widely scattered across and extensively used in the USSR for many decades. The controlled nature of the Soviet society allowed for secure operation of the Soviet nuclear complex. However, as soon as the USSR began to disintegrate and pervasive controls have disappeared, security of the Soviet nuclear complex materials became lax and even the knowledge concerning location of some of them became fragmented. This happened against the background of the sharp economic decline and "wrenching societal change" in the states of the former Soviet Union, as well as the lack of public awareness of market values and dangers of various materials. As a result, people that had access to some kind of radioactive materials had a strong incentive to attempt to profit from it, and that led to theft and illicit trafficking.

The earliest known investigated cases of nuclear smuggling reportedly occurred in Switzerland and Italy in 1991, although it is not known whether a connection between the material in those cases and the Soviet Union was established (Mayer et al., 2007). These incidents were quickly followed by others in Germany, the Czech Republic, Hungary and several other Central European countries. The illicit trafficking phenomenon became so widespread that the IAEA established, in 1995, the Illicit Trafficking Database (ITDB, renamed the Incident and Trafficking Database in 2012) to record and analyze its member states' reports of illicit trafficking and other unauthorized activities involving MORC. The ITDB has indeed registered about 40 cases related to trafficking or malicious use, including scams, between 1993 (earliest year when data was collected) and 1995 (IAEA, 2020). Many of these cases occurred in Europe or its immediate neighborhood, and some involved HEU and plutonium in various quantities (Zaitseva and Steinhausler, 2014).

Investigations were commenced in response, and the authorities often had questions about the nature of the intercepted material, its intended use, origin and potential trafficking route. In cases that do not involve radioactive material, answering these questions is assisted by forensic science laboratories, but it is not normally possible for them to handle radioactive material. It has become clear that in these new cases forensic analysis would have to be done by nuclear measurement laboratories and research institutes.

The first known official case of nuclear forensic analysis for the purposes of a criminal investigation was triggered by the seizure of 72 uranium pellets in Augsburg, Germany, in March 1992. The pellets were analyzed at the EU Joint Research Centre's Institute of Transuranium Elements (ITU) in Karlsruhe, Germany (currently called JRC Karlsruhe). The laboratory was chosen because of its expertise in analytical methods pertinent to IAEA nuclear safeguards (which provided correct and reliable measurements in this case), as well as available nuclear fuel cycle expertise (which allowed for correct interpretation of results of those measurements). The ITU analysis concluded that the seized pellets were nuclear fuel pellets for a Russian RBMK-type graphite-moderated nuclear power reactor, and identified two possible production plants in Russia and Kazakhstan (Mayer et al., 2007).

Thus, the discipline of nuclear forensics was born. But it was not yet defined, and its processes, protocols, purpose and context were not yet described. The Augsburg case was quickly followed by others, and the need to assist criminal investigations arose not just in Europe, but also in other countries, including the United States and Russia. The instances of nuclear smuggling of material were often international. Perhaps the most high-profile case of the early 1990s involved, first, a seizure of a small sample of PuO₂-UO₂ mixture on July 25, 1994, and then a second, much larger seizure of 363.4 g of plutonium in a similar mixture at the Munich Airport on August 10, 1994. Nuclear material was brought to Munich by a Colombian physician on a Lufthansa flight from Moscow. He was found carrying a suitcase containing 560 g of mixed plutonium and uranium oxide powder (containing 363.4 g of plutonium) and 210 g of enriched lithium metal. The analysis conducted by the ITU revealed that the plutonium was probably produced in a graphite-moderated nuclear reactor at the end of 1979, and that the lithium metal was highly enriched in lithium-6, the isotope required for the deuterium-tritium nuclear fusion utilized in thermonuclear weapons (Edwards, 1994; Mayer et al., 2019).

It became clear that nuclear forensics needed an international dimension.

International mechanisms of nuclear forensics

While materials outside of regulatory control certainly exist and can be moved within territories of individual countries, their smuggling across borders is an especially worrisome phenomenon, because it likely demonstrates not just an intent but also a certain capability to conduct criminal acts. It became obvious that combatting the cases of cross-border nuclear smuggling would require international cooperation. This task was eventually undertaken by three international mechanisms: Nuclear Forensics International Technical Working Group (ITWG), the IAEA, and the Nuclear Forensics Working Group of the Global Initiative to Combat Nuclear Terrorism (NFWG).

Nuclear Forensics International Technical Working Group (ITWG)

In May 1995, the US Department of Energy (DOE) proposed holding an international conference on the role of nuclear forensics in addressing nuclear smuggling. The "International Conference on Nuclear Smuggling Forensic Analysis" met in November of 1995 at the Lawrence Livermore National Laboratory in the United States, with more than 70 scientists, law enforcement officials, intelligence and policy-making professionals from 14 countries and organizations in attendance. That meeting came up with a proposal to establish an ongoing forum for international technical cooperation in nuclear forensics by forming a Nuclear Smuggling International Technical Working Group, subsequently renamed the Nuclear Forensics International Technical Working Group (ITWG) (Niemayer, 2019). Two of the founding co-chairs of the ITWG, Lothar Koch and Sidney Niemeyer, explained in 2002 their vision for the group's goal: to "develop a preferred approach to nuclear forensic investigations that is widely understood and accepted as credible" (Fedchenko, 2017). They also formulated the elements of the group's work program aimed at achieving that goal: the development of procedures and protocols for the collection and preservation of evidence, and for laboratory investigation; the development of techniques for material characterization; the development of methods and tools, such as nuclear forensics libraries, to assist with the interpretation of the characterization's results; executing inter-laboratory exercises; and facilitating technical assistance to countries on request (Fedchenko, 2017). This vision of the purpose and work of the ITWG remains unchanged to this day, and the structure of the ITWG task groups, described below, reflects it.

As of 2020, the ITWG has developed into a worldwide "informal and unaffiliated association of nuclear forensics practitioners who are dedicated to advancing the scientific discipline of nuclear forensics in order to prevent and respond to incidents involving nuclear and other radioactive material out of regulatory control" (Smith, 2016). The ITWG preserves its informal status, and is able to remain open for participation of all states, as well as organizations and individuals with a recognized role or expertise in nuclear forensics. It is successful in fostering active cooperation and collaboration between members. At the same time, the ITWG has established and preserved its international credibility through ensuring active participation of the world's leading nuclear forensics laboratories and top experts. It has become an international resource for governments and international organizations, assisting them in fulfilling their nuclear security obligations. ITWG's current mission is to identify, socialize and promote best practices in the field of nuclear forensics.

The ITWG's work throughout the year is steered by two co-chairpersons (traditionally, one representing the US government and another the European Commission), and a small Executive Committee. During the year the main work of the ITWG is done in the five Task Groups (TG): the Evidence Collection Task Group, the Exercise Task Group, the Guidelines Task Group, the National Nuclear Forensics Library Task Group, and the Outreach and Training Task Group (Smith, 2016).

The Evidence Collection TG focuses on procedures involved in the safe collection of evidence at a nuclear security event or a crime scene. This TG's output includes guidelines on topics such as "Evidence Collection in a Radiological or Nuclear Contaminated Crime Scene" (ITWG, 2012).

Formulating and executing inter-laboratory exercises has been one of a few primary focus areas of the ITWG work since its inception. The Exercise Task Group's organization of collaborative material exercises (CMXs, called "Round Robin" exercises in the earlier years), in which the nuclear forensics laboratories that elect to participate, analyze the same material circulated by organizers. The results are later compared to identify "lessons learned", but without attribution of the analytical results to a specific lab. The first CMX involved plutonium oxide (1996); the second investigated highly enriched uranium oxide (2001); the third comprised highly enriched uranium metal (2010); the fourth covered low-enriched uranium (LEU) nuclear fuel pellets (2015), the fifth involved two LEU oxide pellets and one "virtual sample" for comparison (2017), and the sixth utilized depleted U metal ingot and one stable Ce metal ingot, each contaminated with a trace amount of weapons grade Pu fluoride (2019). The second and the sixth CMX also included specially planted "traditional" evidence - fingerprints and toolmarks (Schwantes and Marsden, 2020).

The Guidelines Task Group has so far published 13 guideline documents describing "best practices" of using destructive and nondestructive measurement methods for the purposes of nuclear forensics. These guidelines are designed to be widely available and applicable to nuclear forensics laboratories across the world.

The National Nuclear Forensics Library Task Group's purpose is to organize a series of virtual table top exercises that advance and test the concept of nuclear forensic libraries by facilitating comparisons of samples of interest and available data on known materials used, produced, or stored as part of the nuclear fuel cycle. The "Galaxy Serpent" exercises challenge participants to construct a comparative database and subsequently determine the consistency of exercise data with the holdings in the database. As of 2020 the Task Group has conducted four "Galaxy Serpent" exercises.

Finally, the Outreach and Training Task Group works to distribute the ITWG's technical output to individuals, laboratories, organizations and states with an interest in nuclear forensics. The ITWG has an open website that publishes the Guidelines mentioned above, as well as a tool to promote cohesiveness of the nuclear forensics' community across the world—the "ITWG Nuclear Forensics Update" newsletter.

The ITWG's main events are the Annual meetings. They gather a significant number of professionals every year and provide space for participants to exchange information on topics such as recent cases where nuclear forensic analysis was used, national achievements in nuclear forensic practice, new analytical techniques for measurement of radioactive materials, best practices in presentation of analytical methods or collected evidence to non-scientist audiences (e.g. in court), and outcomes of exercises.

The ITWG has received political support and international recognition on a number of levels. First, nuclear forensics was officially recognized as an element of response to nuclear smuggling events as early as at the Group of Seven (G7) Moscow Nuclear Safety and Security Summit in 1996. The ITWG was later also endorsed by the Group of Eight (G8) Non-Proliferation Experts Group (NPEG) in May 1999, and by the G8/G7 Nuclear Safety and Security Group in 2005.

The International Atomic Energy Agency (IAEA)

The IAEA is an international organization within the UN system that was established in 1957. It works to promote the peaceful use of nuclear energy, and to inhibit its use for harmful purposes, including nuclear weapons and, more recently, nuclear terrorism through promoting nuclear security worldwide. However, implementation of a nuclear security regime remains a responsibility of the IAEA Member States. Upon request of its Member States, the IAEA can support them in establishing and maintaining their nuclear security regimes and infrastructures, including nuclear forensic capabilities. One or more of the following tools can be used to achieve this.

First, the IAEA issues international guidance documents on nuclear security, including in its Nuclear Security Series. This includes the general guidance such as "Nuclear Forensics in Support of Investigations" and "Combating illicit trafficking in nuclear and other radioactive material", as well as more specific technical advice, e.g. "Development of a National Nuclear Forensics Library: A System for the Identification of Nuclear or Other Radioactive Material out of Regulatory Control."

Second, the IAEA has specific advice mechanisms able to assist states, upon their request, in applying that guidance or assessing their nuclear security regime in general and their nuclear forensic capabilities in particular. For instance, the IAEA may develop for the states the Integrated Nuclear Security Support Plan (INSSP), reviewing their nuclear security regimes and identifying areas where those regimes need to be strengthened.

Third, the IAEA, by itself or in cooperation with the European Union, the United States, and other countries, can provide training on issues including nuclear forensic awareness, radiological crime scene management and nuclear forensic methodologies.

Finally, the IAEA promotes the quality of nuclear forensics research and cohesion of research teams through a mechanism of coordinated research projects (CRPs) (Smith, 2019).

The Global Initiative to Combat Nuclear Terrorism (GICNT)

The GICNT, launched in 2006 by the United States and Russia, is a voluntary international initiative of 89 states and six international organizations aiming at strengthening global efforts to prevent, detect and respond to the threat of nuclear terrorism. The GICNT works at a decision-making level, conducting multilateral activities that strengthen the plans, policies, high-level procedures, and interoperability of partner nations. The GICNT has the Nuclear Forensics Working Group that is designed to assist the political leadership in individual countries in their build-up of domestic nuclear forensic capabilities. The group's activities are aimed at raising awareness, developing intergovernmental relationships, conducting joint policy-level exercises and promoting best practices.

The model action plan and the nuclear forensics process

The ITWG recognized very early on that nuclear forensics is a new and emerging discipline that has to apply methods of natural sciences such as physics and chemistry to judicial and other investigative environments. Therefore, nuclear forensics had to be built up conceptually, starting with definitions. The ITWG was exactly the right international body for this job. The central part of the ITWG's vision to "develop a preferred approach to nuclear forensic investigations that is widely understood and accepted as credible," began to be realized in 1997 when the ITWG started to discuss an action plan (a step-by-step description of a general process) that would be applicable worldwide and would allow professionals to "identify and trace back seized nuclear material from illicit trafficking" (Fedchenko, 2017). In June 2000, the ITWG adopted an early version of such a plan at its meeting in Vienna, and named it the Model Action Plan. It contained both the description of the process and the early definitions underlying the discipline of nuclear forensics. It was published initially as a US government document in 2004, and then, with some updates, became an integral part of the IAEA guidance documents on nuclear forensics in 2006 and 2015 (Dudder et al., 2004; IAEA, 2006). The contemporary version of the Model Action Plan is given in Fig. 1.

The nuclear forensics process begins at the site of a nuclear security event, in this case referred to as a "radiological crime scene." At this stage, forensic analysis is a part of a large set of necessary activities included into the radiological crime scene conduct of operations. While it is important that all responders are aware of forensic examination needs, such as the integrity of evidence and preservation of its later admissibility in a courtroom setting, those needs are secondary to safety and security of all involved personnel and the general public. At this stage, the nuclear or other radioactive material found on the scene should go through the *first* stage of the nuclear forensic analysis—categorization or identification. *Categorization (identification)* is the quick assignment of the material of interest for further investigation that determines its further handling, for example, modalities of transportation or an ability of a certain lab to accept it. It is conducted to identify potential nuclear security implications and risks to personnel and the public. For example, a large cache of HEU intercepted in a sting operation would have different implications than an abandoned radioactive source. Transportation of materials to laboratories usually happens after this stage.

Results of material categorization serve as input to the forensic examination plan that is then drafted by investigative authorities—together with "traditional" and nuclear forensic laboratories. The forensic examination plan describes the sequence and requirements to the examinations that need be conducted in order to support a potential criminal prosecution or other legal action. The plan is based on specific questions normally defined by investigative authorities (IAEA, 2015a).

A nuclear forensic analytical plan is developed on the basis of the forensic examination plan to define the specific types and sequence of measurements to be performed over a nuclear or other radioactive material or over evidence contaminated with radionuclides. A nuclear forensic analytical plan then guides the *second* stage of nuclear forensic analysis—characterization.

Characterization is the determination (i.e. measurement) of a sample's characteristics. It may involve (depending on the plan) measurements of physical, chemical, elemental and/or isotopic characteristics of the material in the sample.

Fig. 1 Nuclear forensics model action plan: A process which supports an investigation of a nuclear security event. *Note:* Background shading indicates the transition from radiological crime scene management to nuclear forensics. IAEA (2015) Nuclear forensics in support of investigations. IAEA Nuclear Security Series, p. 7.

Table 2 Categories of characteristics of materials or items subject to measurement (Moody et al., 2014; IAEA, 2015a; L'Annunziata, 2020; Fedchenko, 2015).

Category of characteristic	Characteristics	Commonly used characterization techniques
Physical	Sizes, shapes and textures of solid objects Characteristics of powders: particle size distribution; morphology of individual particles Characteristics of liquids	Visual inspection, photography, dimensional and weight measurements, color, optical microscopy, Scanning Electron Microscopy (SEM), radiography
Chemical (molecular)	Chemical form of nuclear or radioactive material Non-radioactive chemicals used in the nuclear fuel cycle	X-ray spectrometry, XRD, Fourier transform infrared spectroscopy
Elemental	Major elements constituting the sample (if not clear from determination of chemical composition) Minor elements ^a Trace elements ^b	XRF, chemical titration, controlled potential coulometry
Isotopic	Isotopic composition of nuclear materials Isotopic composition of non-nuclear materials	Gamma spectrometry, alpha spectrometry, multiple mass spectrometry methods (e.g. inductively coupled plasma mass spectrometry (ICP-MS), thermal ionization mass spectrometry (TIMS), secondary ion mass spectrometry (SIMS))

^aMinor elements are usually those intentionally added to the material in small quantities to improve or change its physical or chemical characteristics.

^bTrace elements are usually added unintentionally during material production or manufacturing; e.g. machining of uranium metal with steel instruments will leave traces of iron and chromium behind.

For example, characterization of a hypothetical intercepted fuel pellet will likely include at least measurements of its size, shape and surface roughness, chemical composition (e.g. uranium oxide or metal), and isotopic composition (e.g. natural or enriched uranium) (Fedchenko, 2015; IAEA, 2015a). Most common techniques used for characterizing materials in this context as well as their purpose is discussed in Table 2. The ITWG has published on its open website specific guidelines on the use of some of these techniques in the nuclear forensic context.

This stage of characterization produces results of measurements (“analytical results”) in the form of raw data, e.g. numbers or photographs. Such data is rarely useful by itself for answering questions put forward by investigative authorities. In order to make use of it, the data has to be transformed into meaningful information. This is done at a *third* stage of nuclear forensics—*interpretation*.

Nuclear forensic interpretation is defined as “the process of comparing and associating sample characteristics with existing information pertaining to types of material, and origins and methods of production of nuclear or other radioactive material, or with previous cases involving similar material” (IAEA, 2015a,b).

This process utilizes two concepts crucial for nuclear forensics—nuclear forensic signatures, and national nuclear forensic libraries. Nuclear forensic signatures are, in essence, meaningful combinations of material characteristics. The IAEA defines them as “a set or sets of data characteristics of a given sample of nuclear or other radioactive material that may enable the sample to be identified as being consistent with, or as not being consistent with, particular nuclear or other radioactive material used, produced or stored in a State by way of either exclusion or inclusion” (IAEA, 2018).

The signatures are useful because the whole nuclear fuel cycle can be imagined as a flow of nuclear materials through nuclear facilities, each of which by definition transforms the material in some way and, therefore, leaves in the material some information about its history and possibly intended future. Even if nuclear material is simply stored, the process of radioactive decay ensures that the “parent” radioactive isotopes decay into “daughter” isotopes and their ratio may in principle be used to determine the “age” of the material and, possibly, the length of the storage time. In other words, with nuclear material moving through the nuclear fuel cycle, nuclear forensics signatures are being constantly introduced to and erased from it. This fundamental consideration is a nuclear forensic version of the famous Locard’s exchange principle used in “traditional forensics”: “whenever two objects come into contact with each other, they transfer material from one to the other” (Shaler, 2011).

A single nuclear forensic signature is not normally enough to identify a specific sample uniquely from known classes of similar materials. Nuclear forensics laboratories would, therefore, use multiple signatures to increase their confidence in the results of the nuclear forensic interpretation process. In addition, as indicated in Fig. 1, forensic analysis of any kind may be iterative, in the sense that the results of interpretation stage may reveal the need to get back to the characterization stage and conduct additional measurements in order to answer questions put forward by investigative authorities.

To facilitate the use of nuclear forensic signatures in individual states, the ITWG and the IAEA have developed a concept called the National Nuclear Forensics Libraries (NNFL). A NNFL is a national system for the identification of nuclear and other radioactive materials found out of regulatory control (MORC). It should contain, in an available form, reference data on nuclear and other radioactive materials produced, used, or stored within a State, as well as be connected to appropriate experts able to interpret that data. An NNFL enables the use of nuclear forensic signatures to compare existing data on known materials and data obtained from analytical measurements of samples of MORC or, possibly, data provided by other states (IAEA, 2015a). Implementation of this concept is much more straightforward in countries with a smaller nuclear fuel cycle. In some cases, an NNFL would look, for instance, at a list of radioactive sources existing in the state, if that is the extent of that country’s use of radioactive materials.

Thus, at the stage of nuclear forensic interpretation, the data from the characterization stage is interpreted and converted to usable information with the help of nuclear forensic signatures, nuclear forensic libraries, calculations, and subject matter expertise. The product of this fourth stage is nuclear forensic findings, i.e., typically, determinations on material origin and history. Because nuclear forensic findings may be used in legal proceedings or to identify nuclear security vulnerabilities, they are expected to be defensible (e.g. in court), and, therefore, have to be arrived at using arrangements that would allow their use in a specific country. Such arrangements often include the use of validated measurement methods and certified reference materials, reliance on demonstrated competencies, adherence to chain of custody and implementation of quality assurance and quality control procedures (IAEA, 2015a,b).

The final, fifth, stage of the process involves combining nuclear forensic findings with other aspects of the investigation (see Fig. 1), including traditional forensic findings, allowing conclusions to be drawn about the associations between the material and people, places, events and production processes.

Introduction

Cultural heritage is the legacy of physical artifacts and intangible attributes of a group or society that is inherited from past generations and maintained for the benefit of future generations. Protecting the world cultural heritage by maintaining the physical integrity of cultural assets has become a consensus for the entire technical and scientific community. Many analytical techniques used for examination, characterization, analysis, preservation, consolidation and conservation of cultural heritage artifacts, are grounded on ionizing radiations. Among these can be cited radiography using X-rays, gamma photons, neutrons or beta particles, X-ray fluorescence analysis, neutron activation and neutron prompt gamma analysis, ion beam analysis as well PIXE (particle induced X-ray emission), and synchrotron radiation-based characterization or analysis techniques.

The knowledge and understanding of the composition of materials and the processes of manufacturing of ancient or modern artifacts has been significantly improved by the application of scientific analytical techniques, which provides a scientific basis for conservation and restoration work and benefits preservation and conservation institutions, universities, museums, libraries, etc. being well recognized by a large public.

Treatments of cultural artifact collections for disinfestation and disinfection by radiation processing, or simply irradiation, which use ionizing radiation (usually gamma rays from cobalt-60 sealed sources) have been successful mainly in the tangible materials of organic raw material. Tangible cultural heritage materials include works of art, artifacts in museum collections, books, manuscripts, drawings, archive documents, musical instruments, ethnographic objects, archaeological findings, natural history collections, historical buildings and historical places, monuments and industrial heritage objects. Furthermore, the consolidation technique based on the impregnation by an appropriate resin inside of deteriorated objects made of dry or waterlogged wood, porous stones or other fragile materials, also uses gamma irradiation to promote a polymerization process. This technique uses organic polymers with high molecular weight such as polyethylene-glycol enabling to consolidate and to save deteriorated precious artifacts that can be presented to the public in cultural institutions. Commonly, before the consolidation process, the treated artifacts become more resistant to mold or insect attacks.

To this end, the IAEA has been collaborating with the community engaged in the preservation of cultural heritage through research programs, training of scientists, and especially with publications addressed to the development and application of analytical techniques and techniques based on ionizing radiation (radiation processing) for conservation of historical and cultural artifacts. Recently, the dissemination of this knowledge to curators, conservators/restorers, conservation scientists, and students has aimed to improve the global efficiency of the safeguard of our common cultural heritage (Fig. 1).

Ionizing radiation treatment of cultural objects and archived materials

Biodeterioration of tangible cultural heritage objects

Tangible cultural heritage objects are mainly made of wood, leather, textile or paper. Since these materials are basically natural polymers, they are vulnerable to environmental aggressors. Among the physical and chemical agents of deterioration found in the environments are water, oxygen, polluting gases from the atmosphere, acids, temperature, and light. However, the deterioration of artifacts is mostly due to the biological aggressors as well microorganisms and insects (Fig. 2).

Fig. 1 Overview of nuclear techniques to characterization and preservation of cultural heritage objects and archived materials.

Natural disasters

Insects & Fungi attack

Fig. 2 Natural disasters promoting biological attack in tangible materials.

Degradation due to physical-chemical factors evolves slowly and seems to be dependent on noxious exposure intensity, while during an active biological attack the artifact degradation evolves with high speed. In the last case, the conservation prime target must be to stop the degradation. It is important to notice the synergism between improper physical—chemical conditions and the development of biological aggressors.

A preventive conservation plan, including the regulation of microclimate, can be efficient against physical and chemical degradation factors. Usually, controlling the environment can be sufficient to obtain control of biological factors, but only if their attack was not started.

Once the biological attack is underway, each object has to be treated, since the aggressors are present inside the artifact in the active biological form and take it as nutrient. Then, interventive conservation actions are necessary for disinfection because fungi, bacteria and insects have a complex life cycle, including dormant stages resistant at various biocides and unfavorable living conditions (IAEA, 2017).

Biodegradation takes place when insects are present. An example is provided by the ecological food chain involving termites. These insects are xylophages for excellence. They destroy the wood, but they do not have the intrinsic ability to break down cellulose. To overcome this lack of ability, termites carry microorganisms in their digestive tract that produce cellulolytic enzymes. The insects do not feed on the cellulose but on sugars resulting from the microorganisms' digestion of cellulose. In this way the termites profit from the metabolic by-products of the microorganisms.

Molds are microorganisms that are part of the kingdom of fungi and differ from members of the common plant kingdom by the absence of chlorophyll and the lack of ability to create energy from sunlight. Variation in the equilibrium of the moisture content of the material can initiate the development of mold in the substrate. The threshold of water content in the substrate for mold growth seems to be non-uniformly defined, and therefore different threshold levels of relative humidity can be found in literature: 50–60%, 65–70%, 70 and 75% (Thomson, 1986). They are incapable of synthesizing organic components from inorganic ones and, therefore, need carbon as a main source to grow. Most of the mold families are saprophytes (i.e. they are capable of deteriorating plant and animal substrates). The color of the mold is based on the substrate on which it grows. If the level of moisture in the environment drops, mold species are capable of entering a dormant stage in which they are inactive and are therefore able to survive (Great-house and Wessel, 1954).

Mold not only affects archival and library materials, but also affects occupational health through infections (mycoses), allergic reactions and toxic effects (mycotoxicosis). Some families are extremely poisonous and even carcinogenic. *Aspergillus flavus* is one such mold. In 1990 a deadly mold species was found in the cellars of the New Museum of Contemporary Art in New York. Once killed, mold can still be dangerous because of substances remaining in the substrate (Libert, 2013; Nyberg, 1987).

Considering biodegradation, mold, for example, causes an irreversible change to cellulose based substrates. The nutrient matrix for mold in cellulose materials is mainly the amorphous region that also contains polysaccharides such as hemicellulose. Owing to the presence of excess moisture, the fibers swell and become more attractive for mold (Fellers et al., 1989). The enzymes created by the mold deteriorate the cellulose. Mold may also produce radicals which, in the presence of transition metals, will form hydroperoxides (Ritschkoff and Mahlberg, 2001). Based on this progression, two treatments are demanded. First the mold has to be made inactive and then the material needs to receive a preventive treatment to stop chemical deterioration caused by the waste products remaining from the mold, for example removing the residue of disinfection process (e.g. irradiated mold).

Radiation sterilization

The biocidal effect of irradiation was first noticed at the beginning of the 20th century, immediately after the discovery of natural radioactivity. But irradiation treatment, especially for sterilization of medical devices, has only been used in industry for the last several decades and its use is growing. Radiation sterilization, an alternative recommended by the European Pharmacopoeia

(Council of Europe, 2014), has been used more frequently as a final sterilization method. Over 260 million cubic meters of products are sterilized each year using irradiation (GIPA, 2013). It is worth emphasizing that when irradiated under typical conditions (using gamma rays or electron beams (EB) with energies of less than 10 MeV), no radioactivity is induced in the products. Radiation sterilization of medical devices is now a well-defined industrial process, and a large body of knowledge exists on the treatment itself (Fig. 3).

Research conducted to study the influence of irradiation on living organisms led to establishment of a scientific specialty called radiobiology. Other studies were devoted to qualification and testing of materials exposed to radiation, especially plastics and natural polymers (cotton), as well as coatings and adhesives. Engineering studies allowing different various facility designs have been implemented with the objective of optimizing the cost–benefit ratio and improving the production yield, radiation safety or reliability. In addition, guides and standards have been developed covering safety design, installation and exploitation, quality assurance and quality control (IAEA, 2017).

Disinfection of cultural artifacts using irradiation

Irradiation is a transfer of energy from ionizing radiation to the irradiated material. Ionizing radiation has the potential to cause damage in living organisms if they are exposed to excessive levels. Experiments by Bletchly in the late 1950s involving gamma irradiation of xylophagous insects suggested that the biocidal effect of ionizing radiation can be used to stop biodeterioration of cultural heritage artifacts (Bletchly, 1961, 1962). It has been scientifically established that biological response is proportional to dose. The materials remain the same as they were before the irradiation treatment, only decontaminated. Treated materials do not retain radiation and, therefore, cannot irradiate people handling them. In addition to being used to disinfect cultural heritage artifacts, ionizing radiation (e.g. X-rays and gamma rays) is used in radiotherapy (medical) and for non-destructive testing of objects such as cultural artifacts (gamma radiography). The energy transferred modifies the material structure only at the molecular level. The irradiation effects depend on the chemical bonds existing in the irradiated material. In metals and inorganic materials, where there are either metallic or electrostatic bonds, the primary effect of irradiation is warming; in certain situations, color changes may occur. This effect is comparable to heating food in a microwave oven. In organic substances, characterized by covalent bonds, irradiation leads mainly to the breaking of the chemical bonds. The more complex the molecule, the more easily the bonds can break. Therefore, for example, bonds in DNA may be broken more easily than those in cellulose. Organic substances are present in both artifacts and their living contaminants; therefore, degradation is expected in both of them. To avoid degradation induced by irradiation process, the dose should be limited to a maximum of 10 kGy to destroy mold. For many materials, irradiation contributes less to deterioration than mold. The radiation dose (D) quantifies the transfer of energy during the irradiation. It is measured in units called gray (Gy). The multiple kGy (kilogray) is often used. The intensity of all disinfection effects and side effects, is dose dependent. The irradiation disinfection of cultural heritage is an acceptable intervention method, because doses for disinfection are lower than doses producing significant side effects.

Radiation processing has become a mature industrial branch involved in vital economic areas (medical, electrical, food industry, etc.). This increased confidence in the use of radiation treatment for decontamination of cultural heritage artifacts (Fig. 4).

Recommended treatment doses

There are two different of dose range levels that can be recommended for irradiation treatment related to disinfestation and disinfection. The dose for disinfestation of insects is lower than that for disinfection of fungi (e.g. mold). This is based on the complexity of the DNA structure of the species; complex DNA is more easily degraded than simpler DNA (IAEA, 2017).

Fig. 3 A typical panoramic, Cobalt-60 wet storage Multipurpose Gamma Irradiation Facility (IPEN, Brazil).

Fig. 4 Painting and ethnographic sculptures disinfected by gamma radiation at the Multipurpose Gamma Irradiation Facility (IPEN, Brazil).

Insects

In the case of an insect attack, the recommended treatment dose is around 0.5 kGy, but can be up between 2 and 3 kGy depending of the attacked material. This dose is also includes the eradication of insect eggs (Fig. 5). Treatment with 2–3 kGy can be recommended for furniture (wood) that has been stored in inadequate conditions of temperature and humidity for a not too long period. In uncontrolled environmental conditions, a fungal attack can occur simultaneously with an insect attack. Therefore, the range of dose between 2 and 3 kGy is too low for disinfection of all kinds of fungi that can remain and even form a basis for a new infestation by insects. Thus, the use of 2–3 kGy is not recommended if the artifacts are reintroduced after treatment into a non-controlled environment. There is a serious risk that a 2–3 kGy treatment may be ineffective in warm and wet climatic conditions. This is because the termites feeding system is based on a symbiotic relationship with certain microorganisms (IAEA, 2017).

Mold and overall treatment

A treatment with a maximum dose of 10 kGy can be considered as a reference dose for overall disinfection of cultural heritage artifacts. At this level of dose, eradication of fungi occurs. The dose applied to a batch of materials should be considered as an average dose. The final dose depends on the homogeneity of the batch density. Therefore, it is preferable that high density materials are not combined in the same batch with low density materials. Thus, if possible, materials should be classified into batches by density.

The larger the object is, the larger the difference between $D_{\min}$ and $D_{\max}$. Effective distinction should be ensured by $D_{\min}$, and $D_{\max}$ must not exceed the dose value at which side effects become unacceptable. Dose can be measured by means of dosimetry. Dosimetry can estimate the geometric parts of the artifact that get $D_{\min}$ and $D_{\max}$, respectively. The values $D_{\min}$ and $D_{\max}$ are dependent on each other for any given radiation geometry. The irradiation time is chosen in order to obtain the $D_{\min}$ (disinfection effectiveness).

Based on research, an average dose of 8 ± 2 kGy can be set for effective disinfection. This dose is sufficient to eradicate most fungi and will have minor side effects on the irradiated materials. Irrespective of these recommended doses, the conservator and the staff of the irradiation facility may decide to use another average dose. This dose can be lower or higher than the recommended dose (IAEA, 2017).

In the case of artifacts subjected to flooding, microorganisms—and fungi in particular—develop explosively in conditions of excessive moisture. This happens frequently in the case of artifacts that have been subjected to flooding and have remained after the flooding in an environment with a high moisture content. Also, the conditions of storage between the time of the flood and

Fig. 5 Large scale disinfestation of books by gamma radiation at the Multipurpose Gamma Irradiation Facility (IPEN, Brazil).

treatment may encourage the growth of mold. Therefore, a dose of 10 kGy has to be considered, and a dose higher than 10 kGy could be taken into consideration in special situations. Up to the present time, irradiation disinfection has been successfully applied to several cases to preserve materials that had contact with floods, war and poor storage conditions, and for very complex artifacts such as mummies (Fig. 6).

Consolidation of organic materials using radiation technology

The technique for consolidation of porous materials, such as wood or concrete, was introduced and carried out in the 1960s world-wide (the USA, Japan and Europe) by using the process of impregnating these materials by acrylic, vinylic monomers under pressure, and then their in-situ polymerizing or solidifying by gamma irradiation. It was in this period that wood plastic composites were developed, whose main industrial application was flooring in public areas. Very hard surfaces were obtained because the resin fills completely the wooden vessels, giving a densified wood that is much less sensitive to relative humidity.

Application in the field of cultural heritage was initiated in the 1970s in Europe. In 1970, the Grenoble laboratory took up the challenge to consolidate the 19th century mosaic parquet from the ancient Grenoble city hall by dismantling the wooden panels, which were impregnated by the monomer methyl-methacrylate (Fig. 7). During the late 1970s, the consolidation of many degraded wooden artifacts was carried out by using more appropriated radiation-curing resin based on unsaturated polyester and styrene. This latter approach was also implemented in conservation of waterlogged archaeological artifacts that require additional liquid phase exchange steps with the solvent acetone (IAEA, 2017).

Impregnation of wooden artifacts and irradiation

The resin impregnation in degraded wooden artifacts in dry condition is carried out in steel tanks suitable for vacuum and pressure applications. Inside the adapted tank, the artifact must be wedged on its support to avoid floating in the resin bath, and then a low vacuum is set up (around 1 mmHg) during several hours to extract the air from the wood pores. Liquid resin then fills the tank by

Fig. 6 The mummy of Ramses II disinfected by gamma radiation. IAEA (2017) *Uses of Ionizing Radiation for Tangible Cultural Heritage Conservation*. IAEA Radiation Technology Series no. 6. Vienna: IAEA.

Fig. 7 Left: parquet panel before consolidation treatment; right: impregnation of a series of parquet panels. IAEA (2017) *Uses of Ionizing Radiation for Tangible Cultural Heritage Conservation*. IAEA Radiation Technology Series no. 6. Vienna: IAEA.

vacuum suction until the complete immersion of the artifact in the resin bath. In order to ensure the diffusion of the resin in the core of the artifact, nitrogen pressure is then applied in the tank, in the range of 1–3 bars following the decay state of the wood. The duration is a few hours for thin artifacts to more than 24 h for large sizes. At the end of impregnation, the excess resin is flowed back to the storage tank for further use. This feature is one of the main advantages of the irradiation process: the resin, without any catalyst as mentioned previously, can be reused and stored for a long period at room temperature. Back to atmospheric pressure, the artifact is left to drain inside the tank until no more flowing of resin from the object. Out of the tank, the object is cleaned with textile to absorb any resin residue on the surface and then is wrapped entirely with textile and plastic film prior to irradiation. The artifact can be placed at 10 cm from the panel cobalt-60 source to start the in-situ resin polymerization after putting thin thermocouples inside the object to monitor the temperature, which must not exceed 50–60 °C.

The other advantage of radiation-curing is the temperature control by varying the dose rate. For instance, increasing the distance between the artifact and the panel source will result in lowering the wood temperature. This parameter is important for the behavior of the artifact in terms of potential dimensional variations of the surface area or its internal structure. Thanks to the penetrating power of the gamma rays, the polymerization is performed at each point on and inside the object, resulting in a homogeneous and complete reaction. During the first 48 h of irradiation, cleaning of the surface with a textile and the styrene monomer, plus putting new wrapping textile, are both crucial for the wood aspect without the minimum of residual resin on it or glossy surfaces.

The two faces of the artifact are exposed to the sources for the homogeneity of the absorbed irradiation dose, which is around 30–40 kGy after many days of treatment. This dose range is not harmful for the wood structure. Finally, the consolidated artifact is placed in a ventilated chamber during many weeks to eliminate any residual styrene monomer trapped in the object.

The quantity of resin absorbed by the wood increases its weight correspondingly and gives it a composite wood/polymer structure. The material obtained is hard throughout. Hence, its bulk and its mechanical strength are considerably increased. This gives greater resistance to abrasion and friction at the surface and improves solidity and resistance to shocks.

The densified wood is also unaffected by temperature variations and hardly sensitive to changes in climatic conditions when it is displayed or manipulated indoors. Impregnation darkens slightly the color of wood, depending on its species (broad-leaved species darken more than conifers).

Regarding polychromic sculptures, much care must be taken in testing to be sure of minimizing the interaction of pigment layers with the monomer or resin. The method is obviously avoided if any dissolution of pigment by the resin is detected. In some cases, protection of the pigment layer could be realized by wax application prior to impregnation.

Undoubtedly, this process, using insoluble cross-linked polymer and its maximum resin content, is at the opposite end of the conventional application of diluted solutions of polymers, which are theoretically reversible and film forming in the wood structure. Nevertheless, it could be considered as a useful method for the preservation of many degraded artifacts, the “last chance method,” because of the irreversible characteristic method (IAEA, 2017).

Advantages of irradiation techniques

The use of radiation techniques in the preservation of cultural heritage has specific and indisputable advantages over classical procedures. The first advantage is *harmlessness*. This should be highlighted and explained extensively to counterbalance public resistance to nuclear related areas in general. The nuclear domain is vast, and it is a great mistake, due to the misunderstanding of the application of nuclear energy, to judge radiography (which has undoubtedly improved medical diagnosis), Co-60 radiotherapy (one of the few ways to fight cancer), or sterilization by irradiation (a method that brought considerably cheaper medical devices).

Besides, there are no notable differences between sterilization, food treatment or decontamination of artifacts using ionizing radiation. In all cases, the same technology and the same irradiation equipment can be used. Radiation decontamination is performed in a confined, protected and well surveyed area. By design, such a facility can only be used under strict safety conditions. This technology does not leave any residue in the treated artifact or cause any damage to the environment. The artifacts do not become radioactive. Therefore, there is no risk for conservators/restorers, museum curators and registrars, or irradiation facility operators, and there is no risk to the environment. Side-effects in irradiated materials are avoided if recommended dose limits are set in the process.

Another important advantage is *effectiveness*, because gamma radiation penetrates any material and is effective up to its penetration depth, which depends on the density of the material and the quantity of the load, and the biocidal effect is controlled by a single processing parameter, the absorbed dose, commonly called dose. It can be confidently calculated, delivered at a known level, measured and certified. Radiation decontamination can be described as a process that is inherently effective. It does not depend on the material treated. In all other decontamination techniques, effectiveness is conditioned by the diffusion of a gas or the temperature, and these depend on the type and structure of the treated material. There is another practical consequence of radiation penetration: the artifacts can be irradiated without being removed from the package or container used for their transportation.

A further advantage is the *reliability* of the treatment. This is based on the fact that decontamination effectiveness depends only on the irradiation dose. There are international standards, developed by the International Organization for Standardization (ISO), for all dosimetry systems. Additionally, there is an obligation in industrial irradiation facilities to assure the traceability of dosimetry systems to an international reference laboratory. This is a key part of the certification of the quality management system. The composition and structure of the treated artifact do not influence reliability. It is the same for wood, paper, leather, parchment, textile and others, regardless of their degradation stage. The dose can be accurately calculated at different points in large objects. This makes it possible to irradiate oversized objects as effectively as smaller objects. As a method of remedial rather than preventive conservation, irradiation decontamination is applicable in emergency situations. Industrial radiation processing facilities (designed for

sterilization or food treatment) are best suited in such cases. Disinfection using ionizing radiation takes significantly less time than the classical methods.

Provenance and authentication of cultural heritage objects by radiation analytical techniques

Nuclear techniques have long been considered to be one of the most important research techniques for identifying works of art, due to their great sensitivity and the possibility of discovering features that are invisible to the naked eye (IAEA, 2011).

Provenance

The application of analytical methods to objects of cultural heritage must extract the minimum sample, in the case of destructive techniques, or no sample consumption, in the case of non-destructive techniques. In this case, optical methods, such as ultraviolet (UV) or infrared (IR) spectroscopy, and nuclear techniques became viable for application in research with cultural assets after the dawn of nuclear research reactors. Since the 1970s, neutron activation analysis (NAA) has been recognized as the method for investigating materials of archaeological provenance. This enabled the development of databases of archaeological artifacts, and scientists at the Brookhaven National Laboratory were pioneers in adopting multivariate statistical procedures for the study of ceramics and other archaeological materials (Bieber et al., 1976). The provenance presupposes that differences in the chemical composition between different natural sources overcome the differences within a given source. In this way it is possible to trace the artifacts by their source or to group artifacts from unknown sources (Weigand et al., 1977). In the example of sources being localized and easy to identify, such as obsidian, ceramic or clay, raw materials of known sources are usually characterized and, therefore, artifacts of unknown origin can be compared with the variation of the source group known. The tracing of materials to the place of origin, such as ceramics and clay paste, precious stones, basalt, marble, antique glass, copper and other precious metals, were determined using the trace element digital printing method through the application of a set of nuclear analytical techniques.

The prompt-gamma activation analysis (PGAA) is based on the interaction of a given material with neutrons, followed by the measurement of induced radioactivity. In general, irradiation is performed with thermal neutrons generated in a nuclear reactor and the radioactivity of each radionuclide generated is measured by gamma ray spectrometry. It is a non-destructive method with good precision and accuracy, useful for qualitative and quantitative multi-element analysis of the main elements, minor elements and trace elements, in archaeological materials. PGAA is particularly sensitive to light (low *Z*) isotopes, such as hydrogen (H) and boron (B), in addition to cadmium (Cd), mercury (Hg) and rare earth elements and also some bulk elements, such as carbon (C), nitrogen (N) and sulfur (S) can be quantified (Sajó-Bohus et al., 2006; Zoeldfoeldi et al., 2006).

Provenance investigations may rely on the complementary time-of-flight neutron diffraction (TOF-ND), which provides a direct and comprehensive examination of the structural properties of materials, such as ceramics, pigments, stones, marbles and metals, with information about the composition of phases, crystalline and magnetic structure, microspheres and texture, that is, whether or not the grains have a random or preferred orientation. The microstructure of the material is related to the properties of the material and the manufacturing process. Quantitative Rietveld analysis is used for data processing for phase identification, determination of the crystalline lattice, quantitative evaluation of mineral composition and texture analysis. In this way it is possible to understand the representation of the orientation of grains that have been changed in a sample body due to, for example, casting, rolling, hammering or heating of the production process. Therefore, if historical manufacturing techniques are known, texture maps can also help to distinguish genuine from fake artifacts (Grazzi et al., 2009; IAEA, 2011; Kockelmann et al., 2006).

Authentication

One of the problems that affects particularly the artifact trade and has a considerable economic impact is the forgery of cultural heritage objects. In this case, scientific investigations to study composition or age are the only definitive tools to clarify the authenticity of materials in a reliable way, since often the forgery perfectly resembles the original object. The methods already described so far have the potential to also help with authenticity investigations. Other methods, such as ion beam analysis (IBA) techniques, include particle induced X-ray emission (PIXE), particle induced gamma ray emission (PIGE) and Rutherford backscattering (RBS), allow obtaining data on the elemental composition of large objects without affecting the integrity of the materials. Although the analysis is from the surface, adjusting the energy of the proton beam allows information to be obtained in deeper layers of the material. National museums and research institutes, such as the Accélérateur Grand Louvre d'analyse élémentaire (AGLAE) facility at the Louvre Museum in Paris, France, the Laboratory of Nuclear techniques for the Cultural Heritage (LABEC) facility at National Institute for Nuclear Physics (INFN), Florence, Italy (Mandó, 2009) or the IBA facility at the Forschungszentrum Dresden, Germany, have exclusive accelerators for the investigation of cultural heritage and art objects. A detailed survey of available accelerator based analytical techniques was compiled by the IAEA in 2005 (Calligaro et al., 2004; IAEA, 2007, 2011; Jembrih-Simbürger et al., 2004; Mandó, 2005).

The need to prove the authenticity of cultural heritage objects arose from the spread of forgery of cultural heritage artifacts in museums and private collections. The demand for scientific techniques to identify fraud is related not only to the economic value of the cultural asset, but also to the historical, cultural, aesthetic and scientific meanings. In this sense, the techniques based on

nuclear energy certainly contribute to prove the authenticity of cultural heritage assets and are based on principles of forensic science (IAEA, 2011; Stanish, 2009).

Dating

A particular method for proving authenticity is carbon-14 dating. Radiocarbon dating depends on the continuous production of a radioactive carbon-14, or radiocarbon, by cosmic rays in the upper atmosphere. The isotope mixes with oxygen to form carbon dioxide, which is filtered to the biosphere and absorbed by plants, which are then consumed by animals. Carbon-14 (half-life of 5715 years) is lost by radioactive decay, but is balanced by constant production by cosmic rays. All living things, plants and animals, have the same concentration of carbon-14. However, when a plant or animal dies, its replacement of carbon-14 by the atmosphere is interrupted. The content of this isotope in the remains of fossils gradually decreases to the point of being undetectable. Still this technology can be used to date materials as old as approximately 50,000 years. Radiocarbon dating procedures measure accurately the carbon-14 content in various materials, and the results of carbon dating can be used to calculate the age of the object of study. The dating system is an indispensable tool in archeology, geology and other earth sciences. Currently, two procedures are used: a radiometric treatment and a treatment with accelerated mass spectrometry (AMS). Presently, some tens of Nuclear Physics laboratories worldwide work on radiocarbon dating, some of them being almost completely dedicated (Mandò, 2005).

For the AMS technique, an insignificant amount of the material sample is required to obtain the dating. This is important when thinking about dating analyses like The Dead Sea Scrolls and the Shroud of Turin. The Dead Sea Scrolls refer to about 1200 manuscripts first found in 1947 in caves on the hills of Qumran on the west coast of the Dead Sea. They range from small fragments to complete Old Testament books. In only a few cases, direct information about the date of writing was found on the scrolls. In all other cases, dating is based on indirect archaeological and paleographic evidence. To verify this evidence, analyses of AMS contributed to determine the radiocarbon ages of selected scrolls and proved the authenticity of the specimens as belonging to the period from 408 BCE to 318 CE (Bonani et al., 1992). The case of the Shroud of Turin was popularly attributed to the mantle that would have covered the body of Jesus Christ after his crucifixion. The first display of the mantle occurred in France in 1353. In 1578, the shroud was brought to Turin and in 1694 was placed in the Royal Chapel of Turin Cathedral. Scientific analysis using AMS attributed that the mantle was probably from medieval times (Damon et al., 1989).

Scientific studies of paintings

The starting point of a scientific study of a painting is to carry out analyses to identify the pigments. For this purpose, X-ray, IR and UV techniques are applied to the stratigraphic layers of the paints. The results obtained in sets with information on the painting technique support the appropriate decisions for conservation treatments.

X-ray radiography in easel paintings reveals the layers of paint, including elements of high atomic number, and allows visualization of the artist technique and allows the identification of the pigments used in the painting (Fig. 8). However, new research possibilities have been discovered with the use of neutron induced autoradiography.

Therefore, with the detailed study of easel paintings, it is possible to identify the materials and techniques used during the artist's creation process and subsequent restoration interventions. In addition, the step of removing the protective varnish, touch-ups and interventions, allows more accurate identification of the original painting (van den Berg, 2002; IAEA, 2011; Keune, 2005; Stanish, 2009; Van Der Weerd, 2002; Wyplosz, 2003).

An analysis of the pigments used in paintings is of the most importance in order to develop appropriate methods for their conservation, as it provides the detailed characteristics of the materials and enables their origins to be determined.

Studies on pigments used in easel paintings have been carried out for many years in various research centers around the world. These surveys contribute to the creation of databases and publication of manuals. (Eastaugh et al., 2004; FitzHugh and Harley, 2002; Genestar, 2002; Hochleitner et al., 2003). Examples of analytical methods used:

- a. X-ray powder diffraction (XRD), NAA, XRF, total reflection X-ray fluorescence analysis (TXRF), scanning electron microscopy with X-ray microanalysis (SEM-EDX), electron probe microanalysis (EPMA), secondary ion mass spectrometry (SIMS), micro-Fourier transform interferometry (μ -FTIR), thermal microscopy, PIXE, PIGE, Mössbauer spectroscopy, Fourier transform spectroscopy, inductively coupled plasma mass spectrometry (ICP-MS) and gas chromatography mass spectrometry (GC-MS)—for identification of organic substances (varnishes, mediums and organic pigments);
- b. Neutron autoradiography to determine the distribution of pigments and fillers used, and microchemical methods and microscopic methods (microcrystallography, microtexture analysis, petrographic analysis and mineral analysis) (Adriaens and Dowsett, 2006; Arbizzani et al., 2004; Demortier and Adriaens, 2000; Denker et al., 2017; Lill et al., 2002; Mandò, 2005; Respaldiza and Gomez-Camacho, 1997).

Currently, new methods of imaging are being developed that use different types of ionizing radiation, such as confocal X-ray microscopy, multispectral illumination methods, thermographic techniques, scanning acoustic imaging, air coupled ultrasound, Raman spectroscopy and imaging, non-destructive synchrotron X-ray diffraction, synchrotron based K edge imaging and others. The neutron autoradiography method continues to reveal a huge potential for studies of paintings. The basic drawback is the high cost of research and the need to have a nuclear reactor for research purposes (Fig. 9). (Calligaro et al., 2003; Denker et al., 2017; Dooryhée et al., 2005; Kanngießer et al., 2003, 2005; Krug et al., 2006; Maev et al., 2008; Mass et al., 2007; Woll et al., 2004).

Provenance of artistic materials

In the case of investigations related to the history of art, it is important to know the origin of the materials incorporated in the works of art, specifically in works of unknown authorship. This can be identified by measuring the concentration of trace elements and the isotopic proportions in the artistic material and in the respective supposed source material. The analyses have revealed that the isotopic relationships of lead from lead white used by artists before 1800 and, specifically, those found in paintings by Dutch, Flemish and Belgian masters, are limited (Fortunato et al., 2005; Keisch, 1971; Keisch and Callahan, 1976). Based on quantitative analyses to date of trace elements in lead white collected from paintings dating from the fifteenth to the nineteenth centuries, it can be concluded that lead white originating from regions south of the Alps, found inter alia in Venetian paintings, shows a higher content of copper and manganese and a lower content of silver and antimony compared with lead white from regions north of the Alps, mainly applied in Northern Europe (Fortunato et al., 2005; Keisch, 1971; Keisch and Callahan, 1976; Panczyk et al., 1992, 2000).

Nondestructive testing of cultural heritage objects

For cultural heritage artifacts or art objects and their component materials, the conservation scientist needs several non-destructive examination, characterization, and analysis techniques to improve understanding of their manufacture, their evolution and degradation during time. This understanding is necessary to give a rational basis for the restoration and conservation of objects.

Non-destructive testing (NDT) (or non-destructive examination—NDE), includes the scope of methods such as photography, endoscopy, radiography, holography, liquid penetrant testing, magnetic testing, Eddy current, infrared and thermal testing (thermography), acoustic emission, ultrasonic testing, leak testing, etc. These methods are widely used in industrial control and generally as complementary ones (Fig. 10).

Special attention should be paid on the different techniques that covers the general term radiography and their advantages to the study of cultural heritage artifacts.

Radiographic examination for the study of a cultural heritage artifacts

From pertinent radiographs of a cultural heritage artifact (often taken from different incidences), it is possible to deduce various information related to:

- Determination of the internal structure of the object: hollow / fill, thickness and steadiness of the walls, homogeneity and heterogeneity of the constitutive materials, presence of structural defects (porosities, shrink holes, inclusions, cracks, slag, bubbles, voids, delamination, corroded or altered zones, etc.)
- Assembling features, nails, screws, welding, brazing, armatures, core pins.
- Repairs: inserts, secondary casting, screws, etc.
- Presence of eventual previous restorations.

These results may also provide pertinent information regarding the conservation state and arguments for eventual consolidation and restoration procedures (Fig. 11).

Neutron radiography

Neutron radiography is seldom used for the examination of cultural heritage artifacts, but it could be a complementary technique if one wants to look for organic materials inside a closed metal or stone object (Fig. 12). The difference between neutron and X-ray interaction mechanisms produce significantly different and often complementary information. While X-ray attenuation is directly dependent on atomic number, neutrons are efficiently attenuated by only a few specific elements like H, B, rare earths, Co, Li, In, Hg, Au, Ag. For example, organic materials or water are clearly visible on neutron radiographs because of their high hydrogen content, while many structural materials such as silica, chalk, aluminum, steel or lead are nearly transparent. The examination must be done in a thermal neutron beam extracted from a research nuclear reactor.

Computer assisted tomography (densitometry)

Computed tomography is a powerful radiographic technique for producing 2D cross-sectional images (and eventually 3D images) of an object from flat X-ray images. The object to be examined is placed on a turntable stage that is between the radiation source (generally an X-ray tube) and an imaging system (an array of radiation detectors or a 2D pixelized detector). The turntable and the imaging system are connected to a computer. The instrument produces primarily a 2D shadowgraph image of the object like a film radiograph. Dedicated software makes it possible to produce cross-sectional images of the object as if it was being sliced and also reconstruction of its internal structure in 3D. This permits to characterization of the internal structure of an object such as dimensions, shape, internal defects, local density (Fig. 13).

In the cultural heritage area, computed tomography is used for the non-destructive examination and study of mummies, metal statues, archaeological objects, musical instruments, among others. Medical tomographs (scanners), industrial tomographs or dedicated instruments can be used for such purposes.

Microradiography and microtomography

This technique was based on the use of the plate of a scanning electron microscope. The very small focal spot (some mm in diameter) of the focused electron beam (up to 100–150 kV) striking an appropriate metallic anti-cathode (Cu, Ag, Rh, W, etc.) permits obtaining a sharp conical beam of nearly monochromatic X-rays. This beam permits to obtain, by direct projective magnification without loss of image sharpness, enlarged radiographic images of the absorption pattern of thin metallographic samples, and thus obtain precise information about the micro-structure of the studied alloy. The first application was dedicated to metallographic studies of refractory alloys for turbojet engine blades. Later on, companies like Pantak (UK), Feinfocus (DE), Kevex (US), Hamamatsu (JP) marketed dedicated microfocus equipment derived from this development. More recently, beams of mono-chromatic high intensity low energy X-rays have been instrumented at synchrotron machines, which permit similar examinations, but also microtomography to study 3D fine structures of samples of metals, stones, ceramics, wood, bone, fossil (Fig. 14).

Introduction

The use of nuclear technologies in modern society is widespread and pervasive, the economic benefits of radiation applications are enormous, and the global market for radiation applications is huge and is increasing rapidly (RadiationAnswers.org, 2020; [World Nuclear Association](#), May, 2017; [Lowenthal and Airey](#), 2001; “The Benefits of Nuclear Technology,” November–December, 1992). However, the benefits of these non-energy nuclear technologies – which include medical and other radioisotopes and radioactive materials – are not widely known or sufficiently appreciated. The standard of living for most people in developed countries would not be possible without nuclear technologies. They are ubiquitous and extraordinarily important in many ways, both large and small, throughout all aspects of life ([Waltar](#), 2004). In fact, Glenn Seaborg, one of the most prominent scientists of the 20th century, stated that even if not 1 W of electrical power had ever been generated from nuclear energy, all of the money invested in the nuclear energy field from the Manhattan Project forward would have been justified many times over by radioisotopes and radioactive materials ([Bezdek and Wendling](#), 1997).

Aside from the generation of electricity, nuclear technologies play a critical role in:

- Maintaining the safety and structural integrity of buildings, airplanes, and roads and bridges.
- Maintaining the health and quality of the foods and liquids people consume.
- Testing and improving motor vehicles.
- Improving health and saving lives, while at the same time reducing the costs of health care.
- Increasing crop yields and improving the health and productivity of farm animals.
- Reducing the costs of energy exploration and production, and increasing energy efficiency.
- Reducing the threat of terrorism in air travel, in public places, and in other venues.
- Controlling insect pests in an environmentally benign manner.
- Controlling and abating air, water, chemical, and solid waste pollution.
- Facilitating R&D breakthroughs in all fields of science, industry, and technology.

It is generally recognized that nuclear power plants produce electricity and that radioisotopes are used in research. However, it is not widely known that:

- One-third of the patients hospitalized every year in many nations are treated with nuclear medicine techniques.
- Many new drugs must be tested with radioactive materials before they can be approved by regulatory authorities and sold to the public.
- Worldwide, industry depends on radioisotopes and radioactive materials for measurement and automation, process development, quality control and testing, and cost reduction. In many cases, there are no feasible substitutes for these materials.
- Many common, widely used consumer products, such as smoke detectors, non-stick pans, and radial tires, require radioisotope methods for their development, production, or operation. For example, smoke detectors rely on a tiny radioactive source to function, and non-stick pans are treated with radiation to ensure that the plastic coating adheres.
- Radioactive materials are used in thousands of applications ranging from bridge and building construction to police work and anti-terrorism, from dating of archeological artifacts to development of agricultural crops.
- The use of nuclear technologies in chemistry has had as profound an impact in that field of science as use of the electron microscope has had in physics.
- Businesses in all fields of industry and commerce rely heavily on nuclear technologies to maintain and enhance their competitiveness in an increasingly competitive world.
- Nuclear technologies have been used to resolve two of the most controversial archeological disputes in recent decades: The Dead Sea Scrolls and the Shroud of Turin.
- Nuclear technologies have been used to estimate the age of the earth and to support the theory that a cataclysmic impact of a huge asteroid was responsible for extinction of the dinosaurs and the evolution of current species, including homo-sapiens.
- Nuclear medicine techniques permit the detection, treatment, and cure of breast cancer and prostate cancer and many other diseases without surgery.
- One-third to one-half of the food produced in the world is lost due to spoilage and infestation between production and consumption, and nuclear technologies can prevent most of this loss.
- Nuclear technologies permit the exploration of space, which would be impossible without small, radioisotope-powered generators.
- Use of nuclear technologies has reduced the number of patients in the USA treated annually using surgery for hyperthyroidism from 3000 to 50.
- Radioactive iodine is the most reliable treatment available for hyperthyroidism.
- Radiography is used to check the welds on virtually all new oil and gas pipelines and to examine the structural integrity of bridges.
- Radionuclides were key in determining the structure of DNA and in unlocking the genetic code.
- Radioactive materials are used to measure pollution in reservoirs and coastal aquifers.
- Pipeline leaks can be detected using nuclear technologies in a matter of days or weeks at a cost of \$40,000–\$60,000; alternative methods can take six months to a year and cost \$1 million, plus many millions of dollars in pipeline downtime costs.
- In recent decades the application of a single nuclear technique – tracers – in one industry – machine tools – has saved the USA economy nearly \$100 billion.

- Nuclear electron beam processing can eliminate the air pollutants that can cause acid rain and global warming, without producing harmful by-products.
- Solid wastes and sewage can be treated with nuclear technologies without using toxic chemicals.

Perhaps most important, in many cases there are no adequate substitutes for nuclear technologies at virtually any price.

The myriad uses of nuclear technologies

Radioisotopes, nuclear power process, ionizing radiation heat and non-stationary power reactors, and other nuclear technologies have numerous essential uses across multiple sectors, including consumer products, food and agriculture, industry, medicine, scientific research, transportation, water resources, and the environment – Fig. 1. These uses are discussed below.

Fig. 1 Global summary of non-energy applications of ionizing radiation. From Kolmayer A, Mario M, Ligtvoet A, Van Barnevald J, Scholten C, and Davé A (2019) *European Study on Medical, Industrial and Research Applications of Nuclear and Radiation Technology*, Contract ENER/17/NUCL/SI2.755660, Luxembourg: Publications Office of the European Union.

Carbon dating

Analyzing the relative abundance of particular naturally-occurring radioisotopes is of vital importance in determining the age of rocks and other materials that are of interest to geologists, anthropologists, hydrologists, and archeologists, among others (American Chemical Society, 2019). Nuclear technologies play a critical role in these analyses.

Consumer products

The function of many common consumer products is dependent on the use of small amounts of radioactive material (World Nuclear Association, January, 2018). For example, smoke detectors, watches and clocks, radial tires, and non-stick materials, among others, all utilize the natural properties of radioisotopes in their design. One of the most common current uses of radioisotopes is in household smoke detectors. These contain a small amount of americium-241 which is a decay product of plutonium-241 originating in nuclear reactors. The Am-241 emits alpha particles which ionize the air and allow a current between two electrodes. If smoke enters the detector it absorbs the alpha particles and interrupts the current, setting off the alarm.

Environmental tracers

Radioisotopes play an important role in detecting and analyzing pollutants. Nuclear techniques have been applied to a wide range of pollution problems including smog formation, Sulfur dioxide contamination of the atmosphere, sewage dispersal from ocean outfalls, oil spills, and other pollution problems (Elliot, 2014).

Fertilizers

Fertilizers are expensive and if not properly used can damage the environment. It is important that as much used fertilizer as possible is “fixed” in the plant matter and that a minimum is lost to the environment. “Labeling” fertilizers with a particular isotope (e.g. nitrogen-15) provides a means of ascertaining how much has been taken up by the plants, allowing for optimal management of fertilizer use (Glibert et al., 2018).

Food irradiation

Approximately 25–30% of food harvested is lost as a result of spoilage before it can be consumed. This problem is particularly prevalent in hot, humid countries. Food irradiation is the process of exposing foodstuffs to gamma rays to kill bacteria that can cause food-borne disease, and to increase shelf life (Singh et al., 2013). In all parts of the world there is growing use of irradiation technology to preserve food. More than 60 countries worldwide have introduced regulations allowing the use of irradiation for food products.

In addition to inhibiting spoilage, irradiation can delay ripening of fruits and vegetables to give them longer shelf life, and it also helps to control pests. Its ability to control pests and reduce required quarantine periods has been the principal factors behind many countries adopting food irradiation practices.

Industrial tracers, inspection, and instrumentation

Radioisotopes are used by manufacturers as tracers to monitor fluid flow and filtration, detect leaks, and gauge engine wear and corrosion of process equipment. Small concentrations of short-lived isotopes can be detected, and no residues remain in the environment (Pandey, 2015). By adding small amounts of radioactive substances to materials used in various processes it is possible to study the mixing and flow rates of a wide range of materials, including liquids, powders and gases, and to locate leaks.

Radioactive materials are used to inspect metal parts and the integrity of welds across a range of industries. For example, new oil and gas pipeline systems are checked and tested by placing the radioactive source inside the pipe and the film outside the welds. Gauges containing radioactive (usually gamma) sources are in wide use in all industries where levels of gases, liquids, and solids must be assessed. They measure the amount of radiation from a source that has been absorbed in materials. These gauges are most useful where heat, pressure, or corrosive substances, such as molten glass or molten metal, make it impossible or difficult to use direct contact gauges.

The ability to use radioisotopes to accurately measure thickness is widely utilized in the production of sheet materials, including metal, textiles, paper, plastics, and others. Density gauges are used where automatic control of a liquid, powder, or solid is important, for example, in detergent manufacture.

Insect control

Crop losses to insects are significant. Despite the widespread use of insecticides, these losses total in excess of 10% globally, and are often notably higher in developing countries. One approach to reducing insect depredation in agriculture is to use genetically-modified crops, so that much less insecticide is needed. Another approach is to disable the insects.

Radiation is used to control insect populations via the Sterile Insect Technique (SIT) (Rossler, 2015). SIT involves rearing large populations of insects that are sterilized through irradiation (gamma or X-rays), and introducing them into natural populations. The sterile insects remain sexually competitive, but cannot produce offspring. The SIT technique is environmentally-friendly, and has proved an effective means of pest management and control even where mass application of pesticides had failed. The International Plant Protection Convention recognizes the benefits of SIT, and categorizes the insects as beneficial organisms (United Nations Food and Agriculture Organization, 2019).

SIT was first developed in the USA and has been used successfully for more than 60 years. At present, SIT is applied across six continents. Since its introduction, SIT has successfully controlled the populations of a number of high profile insects, including mosquitoes, moths, screwworms, tsetse flies, and various fruit flies (Mediterranean fruit fly, Mexican fruit fly, oriental fruit fly, and melon fly).

The most recent high-profile application of SIT has been in the fight against the deadly Zika virus in Brazil and the broader Latin America and Caribbean region (United Nations, April 19, 2018). Following its outbreak, impacted countries requested urgent support from the International Atomic Energy Agency (IAEA) to help develop the established technique to suppress populations of disease-carrying mosquitoes. The IAEA responded by providing expert guidance, extensive training, and by facilitating the transfer of gamma cell irradiators to Brazil. Three UN organizations – the IAEA, the Food and Agriculture Organization (FAO), and the World Health Organization (WHO) – with the governments concerned, are promoting new SIT programs in many countries.

Medicine

There is widespread use of radiation and radioisotopes in medicine, particularly for diagnosis (identification) and therapy (treatment) of various medical conditions (American Nuclear Society, 2014; Patton, 1993). In developed countries about one person in 50 uses diagnostic nuclear medicine each year, and the frequency of therapy with radioisotopes is about one-tenth of this.

Diagnosis

Diagnostic techniques in nuclear medicine use radiopharmaceuticals (or radiotracers) which emit gamma rays from within the body. These tracers are generally short-lived isotopes linked to chemical compounds which permit specific physiological processes to be scrutinized (Center for Disease Control and Prevention, 2014).

Depending on the type of examination, radiotracers are either injected into the body, swallowed, or inhaled in gaseous form. Emissions from the radiotracers are detected by the imaging device, which provides pictures and molecular information. The superimposition of nuclear medicine images with computed tomography (CT) or magnetic resonance imaging (MRI) scans can provide comprehensive views to physicians to aid diagnosis. An advantage of nuclear over X-ray techniques is that both bone and soft tissue can be imaged very successfully.

The most widely used diagnostic radioisotope is technetium-99 m, with a half-life of 6 h, and which gives the patient a very low radiation dose. Such isotopes are ideal for tracing many bodily processes with the minimum of discomfort for the patient. They are widely used to indicate tumors and to study the heart, lungs, liver, kidneys, blood circulation and volume, and bone structure.

Sterilization

Hospitals use gamma radiation to sterilize medical products and supplies such as syringes, gloves, clothing, and instruments that would otherwise be damaged by heat sterilization. Many medical products today are sterilized by gamma rays from a cobalt-60 source, a technique which generally is much cheaper and more effective than steam heat sterilization. The disposable syringe is an example of a product sterilized by gamma rays. Because it is a “cold” process, radiation can be used to sterilize a range of heat-sensitive items such as powders, ointments, and solutions, as well as biological preparations such as bone, nerve, skin, etc., used in tissue grafts (Finkiel, 2016).

There are significant benefits to sterilization by radiation. It is safer and cheaper because it can be done after the item is packaged. The sterile shelf life of the item is then practically indefinite provided the package is not broken open. Apart from syringes, medical products sterilized by radiation include cotton wool, burn dressings, surgical gloves, heart valves, bandages, plastic and rubber sheets, and surgical instruments.

Therapy

Nuclear medicine is also used for therapeutic purposes. Most commonly, radioactive iodine (I-131) is used in small amounts to treat cancer and other conditions affecting the thyroid gland. Cancerous growths are sensitive to damage by radiation, which may be external (using a gamma beam from a cobalt-60 source), or internal (using a small gamma or beta radiation source). Short-range radiotherapy is known as brachytherapy, and this is becoming the main means of treatment. Many therapeutic procedures are palliative, usually to relieve pain (Florida Medical Clinic, June 28, 2016).

A new field is targeted alpha therapy (TAT), especially for the control of dispersed cancers (Kozempel et al., 2018). The short range of very energetic alpha emissions in tissue means that a large fraction of that radiative energy goes into the targeted cancer cells once a carrier, such as a monoclonal antibody, has taken the alpha-emitting radionuclide to exactly the right places.

Plant mutation breeding

Plant mutation breeding is the process of exposing the seeds or cuttings of a given plant to radiation, such as gamma rays, to cause mutations (Beyaz, 2017). The irradiated material is then cultivated to generate a plantlet. Plantlets are selected and multiplied if they show desired traits. A process of marker-assisted selection (or molecular-marker assisted breeding) is used to identify desirable traits based on genes. The use of radiation essentially enhances the natural process of spontaneous genetic mutation, significantly shortening the time it takes.

Countries that have utilized plant mutation breeding have realized large socio-economic benefits. For example, in Bangladesh, new varieties of rice produced through mutation breeding have increased crops three-fold in the last several decades. During a period of rapid population growth, the use of nuclear techniques has enabled Bangladesh, and large parts of Asia in general, to achieve food security and improved nutrition.

Water resources

Adequate potable water is essential for life. However, in many parts of the world fresh water has always been scarce and in others it is becoming so. Isotope hydrology techniques enable accurate tracing and measurement of the extent of underground water resources (Barbieri, 2019). Such techniques provide important analytical tools in the management and conservation of existing supplies of water and in the identification of new sources. They provide answers to questions about origin, age, and distribution of groundwater, as well as the interconnections between ground and surface water, and aquifer recharge systems. The results permit planning and sustainable management of these water resources. For surface waters they can provide information about leakages through dams and irrigation channels, the dynamics of lakes and reservoirs, flow rates, river discharges, and sedimentation rates. Neutron probes can measure soil moisture very accurately, enabling better management of land affected by salinity, particularly in respect to irrigation.

Estimates of the sizes of the global markets for radiation applications

As discussed above, non-energy uses of nuclear technologies are widely used in health, industry, research, and many other areas. The markets for these technologies extends from the nuclear technologies and equipment themselves, to equipment servicing (maintenance, upgrades, training, etc.) and to health, industrial and research products, and services in which they are embedded, and where their specific added value is most often difficult to isolate. This makes evaluating and estimating the market particularly challenging.

Ionizing radiation (IR) technologies rely on charged particles beams (accelerators), X-Rays, or α , β , or γ -rays, and neutrons. It has been estimated that the Ionizing radiation (IR) technologies alone underpin nearly half a trillion dollars' worth of global commerce a year (Hamm and Kephart, 2017). More generally, the non-energy economic impact of nuclear technologies and applications is enormous. For example, the 2019 economic impact of these technologies is estimated to be \$532 billion in the USA and \$233 billion in Japan (Bezdek and Wendling, 1997; Bezdek et al., 2008; Waltar, 2004) (Economic impact estimates converted to USA 2019 dollars by the author).

The evaluation of the IR equipment market is somewhat more straightforward. The global market value of IR equipment is estimated at more than USA \$40 billion per year, with health applications being the most important non-energy sector – see Fig. 1. This global equipment market is attractive, with a high 3–6% annual growth rate and favorable export prospects (Kolmayer et al., 2019). The equipment market is also competitive, driven by constant innovation, which requires substantial investments.

Assessing the global economic impact of such diverse applications is difficult because they are generally embedded within products and services and manufacturing processes and research where their specific added value is difficult to estimate. Nevertheless, as noted, it has been estimated that ionizing-radiation applications of accelerators alone underpin nearly half a trillion dollars-worth of commerce a year, without taking into account their invaluable health benefits (Hamm and Kephart, 2017).

Estimates of the current size of the global markets for radiation applications are presented below.

Food irradiation market

The global food irradiation market currently totals USA \$250 million and is growing at a compound annual growth rate (CAGR) of 5% (McHugh, 2019; Hallman et al., 2016; Lacroix and Follett, 2015). This growth rate is due to increased consumer acceptance since the U.S. Food and Drug Administration (FDA) approved phytosanitary treatment of fresh fruits and vegetables by irradiation. Phytosanitary treatments disinfect traded commodities of potential quarantine pests, and phytosanitary irradiation treatments use ionizing radiation to accomplish this. The food irradiation market in Asia is also growing very rapidly owing to approval of government agencies in India and other countries. At present, over 40 countries have approved applications to irradiate over 40 different foods. More than half a million tons of food is irradiated worldwide annually. For, example about a third of the spices and seasonings used in the USA are irradiated.

Ionizing-radiation equipment market

Global market data are available for the ionizing-radiation equipment market (Kolmayer et al., 2019). The global annual market currently totals about USA \$40 billion and is growing at a CAGR of about 5%. The market consist of the following major segments – data presented in USA \$:

- Health – USA \$32 billion
- Industry (excluding health) – USA \$6 billion, excluding the consumer-products segment, which is likely to be significant
- Research – USA \$2 billion

Healthcare applications are probably the most important non-energy field to use ionizing-radiation tools. The market is driven by Asian markets in particular. Competition in these markets is fierce, with an increasing presence of USA and Asian companies relying on strong domestic markets. Ionizing radiation technologies are used daily in Europe in a number of fields, including health, industry, and research, with significant impact on the health of European citizens, the European economy, and Europe's international influence.

Magnetic resonance imaging (MRI) market

The Magnetic Resonance Imaging (MRI)-guided radiation therapy systems market currently totals nearly USA \$300 million and is increasing at a CAGR in excess of 20% (Eminent Research and Advisory Services, May, 2019). The MRI-guided radiation therapy systems industry has been underpinned by the emergence of advanced technologies in the healthcare and medical devices industries. Increasing adoption of radiotherapy in cancer treatment is fueling demand for MRI-guided radiation therapy systems.

Medical X-ray radiation protection glass market

The worldwide market for medical X-ray radiation protection glass currently totals about USA \$350 million and is forecast to increase at a CAGR of nearly 2% (360 Research Reports, 2019).

Medicine and radiopharmaceuticals market

The medicine and radiopharmaceuticals market currently totals about USA \$6 billion and, driven by the increasing number of successful clinical trials, is increasing at a CAGR of 9% (Fortune Business Insights, December 24, 2019). The market includes PET radiopharmaceuticals and SPECT radiopharmaceuticals, applications in neurology, cardiology, oncology, and other fields, and end users including hospitals, clinics, and diagnostic centers. The major growth factors driving this market include:

- Radiopharmaceuticals are substances that are used to diagnose specific medical problems or diseases, and increasing imaging capabilities and efficiencies have led to a wide product adoption across the world. Increasing numbers of successful clinical trials associated with radiopharmaceuticals are increasing demand for the product.
- Recent drug application area discoveries have showcased promise for the companies operating in the market, and technological advancements in nuclear imaging and their applications in diagnosis of cancer and other serious diseases have opened up a huge potential for growth.
- Growing awareness regarding the adverse effects of chronic diseases, and the need for early diagnosis, are facilitating market growth. The advancements in imaging systems have played a major role in the growth of the market.

The need for early and accurate diagnostic methods, coupled with increasing need for better therapies, is driving the market (Grand View Research, Inc. August, 2018). Increasing incidence of cancer and cardiovascular disorders is also contributing toward market growth, since nuclear medicine has proven to be critical in the diagnosis and treatment of such conditions (International Atomic Energy Agency, 2015). Medical exposures have grown considerably in the past several decades, mostly due to the marked increase in the use of CT scanning and other advanced imaging (United Nations Scientific Committee on the Effects of Atomic Radiation, 2008).

According to the World Health Organization (WHO), the number of new cases of cancer is expected to increase by around 70% over the next two decades (World Health Organization, September, 2018). Globally, about 10 million people die annually from cancer, and cancer accounts for one out of every six deaths worldwide.

Increasing prevalence of cardiovascular diseases is fueling market growth. These diseases account for nearly 20 million deaths annually worldwide. The number is anticipated to exceed 23 million by 2030. An estimated 31% of global deaths can be attributed to cardiovascular diseases (World Health Organization, September, 2017).

At present, radiopharmaceuticals are widely used in the field of oncology and cardiovascular diseases. Ongoing research and studies demonstrating positive results is widening the scope of radioisotope applications for diagnosis and treatment of bone diseases, respiratory diseases, thyroid-related diseases, and conditions of the digestive tract. In addition to these applications, radioisotopes are widely used in radiopharmacology to study drug movement in lab subjects.

Radiation cured products market

The radiation cured products market currently totals about USA \$8.5 billion and is increasing at a CAGR of nearly 7% ([Global Industry Analysts, Inc. April, 2018](#).) The global market for radiation cured products, including adhesives, coatings, inks, and electronics, currently exceeds 600,000 thousand metric tons and is driven by growing awareness of the numerous environmental and performance benefits offered by radiation curing. Also driving growth in the market are innovations in radiation curable chemistries and stringent environment safety norms that encourage environmentally-responsible curing of resins, inks, coatings, and adhesives. The adoption of radcure technology in a broad range of applications is attributed to several advantages, such as more rapid curing and processing time, lower volatile organic compounds emissions, improved physical characteristics, and cost-effectiveness. Construction, furniture, medical, and automotive industries represent attractive end-use markets for radcure technology. Europe represents the largest market worldwide. However, Asia-Pacific ranks as the fastest growing market led by strong Chinese demand for ultraviolet and electron beam curing technologies, which are rapidly replacing traditional methods in several applications such as wood coatings, industrial coatings, and electronics coatings.

Radiation detection, monitoring, and safety market

The global radiation detection, monitoring, and safety market currently totals about USA \$30 billion and is increasing at a CAGR greater than 4% ([Global Radiation Detectors Market by Manufactures, Types, Applications, and Forecast 2019-2024, 2019](#); [Radiation Detection, Monitoring, and Safety Market by Product, Composition, and Application, 2019](#)). The market includes products, such as detection & monitoring and safety equipment, gas-filled detectors, scintillators, solid-state detectors, and various applications in healthcare, homeland security, defense, and industry. The key factors driving the growth of this market include increasing security threats, growing prevalence of cancer worldwide, increasing safety awareness among people working in radiation-prone environments, growing safety concerns following the Fukushima disaster, growing security budgets of global sporting and entertainment events, growth in the number of PET/CT scans, increasing usage of nuclear medicine and radiation therapy for diagnosis and treatment, and use of drones for radiation monitoring.

Radiation dose management solution market

Radiation dose monitoring, dose management, dose recording, and radiation safety technologies include systems to reduce or block dose via barriers or computed tomography (CT) dose reduction technologies such as iterative reconstruction. The global radiation dose management solution market currently totals USA \$250 million and is increasing at a CAGR of over 14%. The market is driven by the increasing adoption of medical imaging equipment. In addition, the demand for cloud-based systems is anticipated to further increase the growth of the radiation dose management solution market.

Factors such as increasing applications of diagnostic imaging modalities and rising prevalence of various diseases are driving the need to conduct medical imaging examinations. In addition, the increasing focus on prevention and early diagnosis of diseases along with the availability of reimbursement in countries such as the UK and the USA will further drive the demand for medical imaging equipment such as picture archiving, communication systems, and radiology information systems. This in turn, will drive the adoption of radiation dose management solution, which captures, tracks, and reports the radiation dose directly from these imaging devices. Thus, the increasing adoption of medical imaging equipment is expected to drive market growth during the forecast period.

Market growth has been primarily attributed to the major drivers such as increasing prevalence of chronic and lifestyle associated diseases, increasing installed bases of radiology equipment, growing geriatric population, increasing regulatory requirements for diagnostic devices, increasing concerns related to radiation overexposure, and growing awareness and initiatives for radiation dose management. The market is expected to grow at a significant growth rate due to the opportunities that lie within its domain, which include technological advancement in medical imaging, impact of cloud-based solutions, increasing adoption of radiation dose management technologies in emerging technologies, and radiation dose management for pediatric procedure. However, there are significant challenges which are restraining the market growth. These challenges include lack of trained and skilled professionals, and lack of benchmarking for dose optimization ([Technavio, 2019a](#); [BIS Research, 2019](#)).

Radiation-hardened electronics market

Radiation-hardened electronics are electronic components, packages and products that have been designed and tested to provide protection against penetration radiation that may, if unimpeded, cause malfunction, damage circuitry, or cause the electronic device to shut down. The global radiation-hardened electronics market currently exceeds USA \$700 million and is increasing at a CAGR greater than 4% ([Global Industry Analysts, 2019](#)).

Radiation safety and protection and shielding applications market

The global market for radiation safety and protection and shielding applications currently totals about USA \$60 million and is increasing at a CAGR greater than 4% ([Technavio, 2019b](#); [BCC Research, June, 2019](#)). The market is driven by a number of factors,

including the increasing number of installations of radiology equipment. In addition, advances in radiation shielding equipment are anticipated to further increase the growth of the medical radiation shielding market.

The adoption of diagnostic radiology equipment is increasing with the growing number of imaging examinations resulting from the high prevalence of chronic diseases. Other factors such as the increasing number of radiologists and high demand for technologically advanced diagnostic radiology equipment are further driving the installation of the radiation equipment. This is increasing the need for medical radiation shielding to minimize the exposure to excess radiation and protect patients from acute health effects. Thus, the increasing number of installations of radiology equipment is a major factor driving market growth.

Radiopharmaceutical and therapeutics market

The global radiopharmaceutical and therapeutics market current totals about USA.

\$17 billion and is increasing at a CAGR in excess of 9% (Laxmi, 2019).

Radiation therapy market

The current global market for radiation therapy, also known as radiotherapy, exceeds USA \$7 billion and is growing at a CAGR of nearly 7% (MarketsandMarkets Inc. July, 2019; Radiotherapy Market by Type, Product, Application and End User, 2019). Radiation therapy uses ionizing radiation, generally as part of cancer treatment to control or kill malignant cells, is normally delivered by a linear accelerator and includes *Stereotactic, Brachytherapy, CyberKnife, Gamma Knife, Tomotherapy, Particle Therapy, and related applications*. Radiation therapy may be curative in a number of types of cancer, such as breast cancer and prostate cancer, if they are localized to one area of the body. Market growth is driven largely by factors such as technological advancements, the need for cancer treatments, the increasing number of conferences and symposia focusing on spreading awareness about the benefits of radiotherapy, and the growing use of particle therapy for cancer treatment. In addition, the increasing adoption of radiotherapy procedures for cancer treatment, increasing use of particle therapy for cancer treatment, and the rising number of conferences and symposia focusing on the advancements in radiotherapy are some of the other major factors driving the growth of this market. The emerging markets, growing government and private investments to meet the increasing demand for cancer treatment, and the improving reimbursement scenario are expected to present a wide range of growth opportunities for market players.

Terahertz radiation devices and systems market

Terahertz (THz) radiation can penetrate fabrics and plastics and is used in surveillance, such as security screening, to remotely uncover concealed weapons and explosives. The global market for terahertz radiation devices and systems currently totals USA \$170 million and is increasing at a CAGR in excess of 31% (BCC Research, August, 2019).

Summary

It is clear that modern society cannot function without nuclear technologies and that the benefits of these technologies are enormous and widespread. International markets for these technologies exceed USA \$500 billion annually and are growing rapidly. For example the global market for:

- Food irradiation is growing at a CAGR of 5%.
- Ionizing-radiation equipment is growing at a CAGR of 5%.
- Magnetic resonance imaging (MRI)-guided radiation therapy systems are growing at a CAGR in excess of 20%.
- Medicine and radiopharmaceuticals is increasing at a CAGR of 9%.
- Radiation cured products is growing at a CAGR rate of nearly 7%.
- Radiation detection, monitoring, and safety is increasing at a CAGR greater than 4%.
- Radiation Dose Management is growing at a CAGR rate of over 14%.
- Radiation-hardened electronics is increasing at a CAGR greater than 4%.
- Radiation safety and protection and shielding applications is increasing at a CAGR greater than 4%.
- Radiopharmaceutical and therapeutics is increasing at a CAGR in excess of 9%.
- Radiation therapy is growing at a CAGR of nearly 7%.
- Terahertz radiation devices and systems is increasing at a CAGR in excess of 31%.

601

This section of Elsevier's Encyclopedia of Nuclear Energy is devoted to the "Social Issues" surrounding the technology. Perhaps no modern technology has been so misunderstood by the public. Initially conceived to address mankind's need for an abundant source of clean energy, its birth with the atomic bomb has for many affected people's attitude toward the technology. When President Dwight D. Eisenhower initiated the "Atoms for Peace" program at the United Nations in 1954, the hopes for the technology were high and aspirational. No one could have imagined how much the fear of radiation affected people's perceptions of the technology. This fear can be understood because of the low level of knowledge about radiation effects by the public and little connection with the contribution nuclear energy can make to de-carbonization of the climate.

Experience to date indicates that nuclear energy, if managed carefully, can be very beneficial and safe in comparison to other energy technologies. Nuclear energy has many attributes that render it a potentially important complement to other energy technologies that do not generate greenhouse gases. If nuclear energy is not considered in the portfolio of other clean energy sources, mankind will suffer great needless harm because of these unfounded but widely held perceptions (Golay, 2021).

This section will explore and hopefully shed light on some of the key social issues affecting the application of nuclear energy for peaceful purposes. Authors of the various sections of this chapter are experts in the areas they cover. The topics that are addressed are:

1. Factors Affecting Public Opinion of Nuclear Energy in the US

A 36-year program of research shows that the majority of the US public favors nuclear energy and this support is even stronger among nuclear power plant neighbors. This chapter draws primarily from that extensive and in-depth program of research on public attitudes toward nuclear energy by Bisconti Research. The long-term trends show that support for nuclear energy is much greater today than it was when the survey program began in 1983. Gender, education, and political affiliation continued to be associated with attitudes. Women are more uncertain about nuclear energy, not more opposed. A stigma attached to nuclear energy may be diminishing, as recent surveys show that the public's view of "public opinion" improved recently.

2. How Innovative Reactors Could Improve Public Acceptance of Nuclear Energy

Society's growing concern about climate change, desire to move more people out of energy poverty, and aim to bring equity to technology deployment have created an opportunity for new, innovative reactor designs, called advanced reactors, to contribute to the global clean energy transition. To realize this opportunity, however, there is a strong need for innovation across the technology space, within social frames, in organizational structures, and in cultivating leadership. There are many reactor designs to choose from, with different types using different technical approaches to resolve the challenges the designers think are most important—including political and social challenges. Each community and country must choose for themselves what they value since the answer is unlikely to be the same everywhere. This chapter examines the case for advanced reactors, summarizes the current state of development, and assesses how technical and social systems must be considered collectively for the best outcomes.

3. Relative Nuclear Energy Health Hazards and Popular Acceptance

Experience to date indicates that nuclear energy if managed carefully can be very beneficial and safe in comparison to other energy technologies. Yet it is perceived by many as being unnatural, highly threatening, and too dangerous to be used. In wealthy democracies this perception has become common over the past 40 years, and experience to the contrary seems not to be able to budge it. This can be understood in terms of the weak state of knowledge of existence of natural radiation on Earth and of low dose radiation health effects and the public perception of high hazard combined with absence of important benefits provided by nuclear technology. Whether these views will cause nuclear energy to be omitted from the technological portfolio to be used in response to impending climate change may be very important in determining how harmful global warming becomes. Nuclear energy has many attributes that render it a potentially important complement to other energy technologies that do not generate greenhouse gases. It is plausible that mankind will suffer great needless harm because of these unfounded but widely held perceptions.

4. Securing Nuclear Power's Contribution to Decarbonization

The results of the MIT study on *The Future of Nuclear Energy in a Carbon-Constrained World* are summarized in this chapter. These results of an electricity generation capacity and dispatch optimization model under carbon constraints demonstrate the opportunity for nuclear across various regions with different renewable resource endowments and costs of nuclear. Nuclear power contributes a firm, dispatchable element to a portfolio of low carbon technologies, which lowers the cost of achieving decarbonization targets. However, high construction costs of nuclear plants in western Europe and the U.S. have undercut this

case. Pinpointed are the key contributors to high cost and identify opportunities for reducing costs. Finally, there is a review of the role for government policy in enabling nuclear energy to contribute to decarbonization.

5. Economics of Nuclear Power vs Other Energy Sources

Two types of costs, total cost and levelized cost of electricity provide much of the economic information necessary to compare competing electricity generating alternatives. Levelized cost is important because it suggests whether the nuclear power plants can compete in the long run against other generating technologies. These other technologies include combined cycle natural gas, coal, hydro, and renewables. This chapter calculates and compares the levelized costs of these electricity generating sources. Also, electric utilities, when making investment decisions, must consider how a specific generating unit interacts with its portfolio of generating assets.

6. Impact of Small Modular Reactors on the Acceptance of Nuclear Power by the Public, Investors, and Owners

The acceptability of nuclear power has varied widely throughout its 60-year history influenced both by externalities, such as regional economic strength, availability of energy alternatives, and political biases, and by the successes and failures of the nuclear industry itself. The nuclear industry is on the verge of introducing a new paradigm in the delivery of nuclear power: small modular reactors (SMRs) that promise to improve on all aspects of design, engineering, construction and operation of commercial nuclear power plants. If fulfilled, these promising benefits can have a significant impact on the acceptance of nuclear power to all stakeholder groups, including the general public, financial investors, and plant owners.

7. The Environmentalist's Dilemma

The environmental movement is facing difficult decisions in the years ahead if they want to maintain their credibility relative to the dangers of global climate change. On the one hand, they aggressively proclaim the dangers of global warming due to manmade increases in CO₂ levels and on the other, reject one of the largest non-CO₂ electricity generating sources – nuclear energy. As a proven performer for over 50 years, nuclear generated electricity is produced by over 440 nuclear plants world wide. Nuclear energy combined with solar and wind can be a winning combination in the battle against global warming. This chapter highlights reasons why major environmental organizations oppose nuclear energy; identifies groups and people who have switched their positions in support of nuclear energy; highlights positions of environmental organizations who support nuclear energy and finally provides environmental and public health reasons for these groups to support nuclear energy. It is hoped that this article will help those who feel uncertain about supporting nuclear energy reasons for actively supporting it as a resolution to the “environmentalist's dilemma.” We conclude with a sentence from top climate scientists in their 2013 letter to the environmental community: said “continued opposition to nuclear power threatens humanity's ability to avoid dangerous climate change.”

8. Nuclear Waste Can Be Disposed of Safely

The disposal of nuclear waste is one of the key issues facing the use of nuclear energy. Many question the feasibility and safety of disposal for tens of thousands of years. Scientists and engineers have recommended deep geological disposal as a final solution. The goal is to keep the radioactive materials safely in geological structures and away from our surface environment. Nature provides us with evidence that geological disposal is possible based on natural reactors that operated several billion years ago. Thus far, there is one geological repository for nuclear waste operating in New Mexico since 1999 at the Waste Isolation Pilot Plant. The United States proposed repository in Yucca Mountain, Nevada was politically cancelled after 20 years of study and the submission of a license application to the Nuclear Regulatory Commission in 2008. The results of the studies and NRC review provide the data and analysis that shows the repository can be safely operated for at least 10,000 years. International efforts in Europe also are making progress with Finland scheduled to open their geological repository which is now under construction in 2023 after a vigorous technical safety review. Thus, to answer the question can nuclear waste be safely disposed, the answer is yes. The big challenge is overcoming political opposition and public concerns.

9. The Sustainability of Nuclear Energy

One can have confidence that uranium and thorium will not be a limitation on the sustainability of nuclear energy. We do not know today the exact locations of the ore bodies containing future sources of uranium and thorium, but the global measurements of supernova nucleosynthesis, geoneutrinos and thermal gradients discussed in this article indicate that those sources are very likely to exist. Furthermore, it is not necessary that we know those precise locations today since the fuel itself will not be needed for several centuries. The geoneutrino measurements indicate that at least 25% of global uranium and thorium are located in the continental crust and the thermal gradient data indicate that these elements are within a few kilometers of the surface. The discoveries of unexpected IOCG deposits indicate that multiple modes for the concentration of uranium exist. The development of chelating ligands for the extraction of uranium from seawater is not yet economical compared to existing mines and *in situ* extraction on land, but the technology places a ceiling on future uranium prices and assures a widely accessible source. Although the quantity of uranium in the oceans is immense, hundreds of times presently identified resources, the oceans are being constantly replenished by rivers which carry dissolved uranium from the continental crust.

10. Non-Proliferation Aspects of Nuclear Energy

In December 1942, the Chicago Pile-1 (CP-1) demonstrated the feasibility of self-sustaining nuclear chain-reaction. However, the public realization of the enormous power of nuclear energy was not until the detonation of a nuclear weapon in August 1945. Ever since the dawn of the nuclear age, the potential for peaceful uses of nuclear energy often raised concerns that the potential spread of nuclear weapons would be catalyzed by a civilian nuclear power program. There is also the possibility of theft of fissile material or nuclear technology by non-state entities or terrorists. Though nuclear power reactors and nuclear

weapons operate under different conditions, they rely on a similar scientific basis and use similar materials and technologies. This article discusses some of the activities and characteristics related to curtailing and deterring proliferation associated with worldwide deployment of nuclear energy; that is, the non-proliferation aspects of nuclear energy from the perspective of policy, regulation and design.

11. Public Images of Nuclear Energy

Radioactivity and nuclear energy were entangled from the outset in an ancient web of associations: cosmic secrets of transmutation and life-force, mad scientists with death rays and monsters, apocalyptic destruction, a future golden age. Fear of nuclear war reinforced the links to psychologically profound symbols. The anti-nuclear-bomb movement taught that any trace of a radioactive substance is horrible contamination and authorities are untrustworthy, convictions that carried over into the anti-nuclear-reactor movement. These associations have lingered, less consciously, into the present. Ameliorating excessive public fear of nuclear radiation requires sophisticated communication techniques.

12. Societal acceptability of geological disposal: a crucial issue—See Chapter 00622

13. Nuclear Waste Can Be Reduced by Recycling and Transmutation

This article first reviews the problem of radioactive waste (RW) in particular the problem of long-lived high-level radioactive elements contained in spent nuclear fuels from nuclear reactors. In this respect, it discusses the various possible options for their management and analyses more particularly the option of reprocessing these spent fuels that allows the recycling of the nuclear materials recovered after this reprocessing operation (uranium and plutonium). Main conclusions of this paper are reprocessing makes sense from the standpoint of recycling because it allows a much more efficient use of natural uranium to produce energy. Reprocessing is important to high level nuclear waste disposal since it greatly reduces their volume and puts them in a more stable configuration making it more difficult to release into the environment. Additional steps can be taken to make risk of disposal even lower by partitioning and transmutation of minor actinides and certain fission products. Regardless of all the above, a repository for high level nuclear waste is still needed whether for once through or reprocessed waste.

14. Floating Nuclear Plants to Improve Economics, Safety, Siting and Proliferation Resistance

Floating nuclear plants have been around for decades, first powering nuclear submarines and aircraft carriers. The first “commercial” application was in 1967 when a reactor was placed in a converted liberty ship in 1967 to provide power to the Panama Canal. Today many countries are developing commercial nuclear plants to provide power to remote areas as well as grid power for nations that may not have the technical infrastructure to support nuclear energy. Many designs are being developed from subsurface submarines without propulsion to floating barges to offshore floating platforms. These concepts attempt to address many issues some of which are social, such as public acceptance while others are more economic, in that it is expected that factory fabrication in a shipyard using modularity principles can lower overall cost and improve quality. Concerns about safety, security and non-proliferation aspects of floating nuclear plants are addressed showing numerous improvements over land based nuclear plants.

15. The Case for International Fuel Cycle Centers

Expansion of nuclear energy is a part of the world’s battle against climate change. The International Panel on Climate Change recognizes the importance of nuclear energy as a contributor to energy supply. A key element in the production of nuclear energy is the “fuel cycle” which is what is required to make nuclear fuel and treat used nuclear fuel. The fuel cycle includes mining, milling, enrichment and fuel fabrication in the “front-end” and used fuel management in the “back-end.” In future nuclear energy system the “back-end” involves recycling the used nuclear fuel to extract the remaining useful materials for reintroduction into the reactors, and to process and dispose of the nuclear waste. In the recycling process, the used fuel needs to be chemically separated to extract the uranium, plutonium (and possibly minor-actinides) for reuse. This extraction process and enrichment is a proliferation risk since these materials can be used to make nuclear weapons. The goal of the non-proliferation regime is to prevent such diversions while not denying countries the benefit of using nuclear energy. International fuel cycle centers have been proposed to address this problem. These centers would be centrally located around the world to enrich natural uranium, receive used fuel, reprocess it and recycle it into new fuel and embed the left-over nuclear waste in a stable glass form for geological disposal. Such a center would avoid the need for each country to develop enrichment plants which are a direct line to a nuclear weapon. It would also avoid the need for building reprocessing plants and help address nuclear waste disposal by creating a greatly reduced and stable waste form. The concept calls for the host nation to have the necessary skill set and infrastructure to prevent diversion. The developing nation seeking the benefits of nuclear energy would purchase fuel cycle services from the center, ship the used fuel to the center for recycling and have the nuclear waste returned to them for disposal or to a centralized disposal facility as discussed in chapter “The Case for International Fuel Cycle Centers.” If such a scheme was to be implemented, the proliferation risk would be greatly reduced. France has established a small version of such a center with its complex at LeHague which is reprocessing used fuel from France and Japan for reuse. The success of the international fuel cycle centers depends on security of supply not subject to political disruptions.

16. The Case for International Waste Disposal Centers

There have been several proposals for regional and international repositories for disposal of high-level nuclear wastes, and in 2003 the concept received strong endorsement from the head of IAEA. The European Commission is funding studies to assess the feasibility of European regional waste repositories. Arising from these studies, 14 EU countries resolved to set up a European Repository Development Organisation (ERDO) to collaborate on nuclear waste disposal. A similar initiative is under way for the Middle East and North Africa. In May 2016 a high-level commission in South Australia recommended establishment of an international repository there. Since 2009 the International Framework for Nuclear Energy Cooperation (IFNEC) has focused

on possible multinational repositories for their safety, security and environmental benefits, especially for the approximately 20 countries with less than 3000 tonnes of used fuel in storage where they would be most appropriate. However, in 2019 IFNEC suggested that it was not timely to develop a multinational repository until national repository projects were more advanced.

17. Mankind Benefits of Nuclear Energy and Radiation

There are multiple uses of nuclear energy and radiation. They may be broadly classified into those using heat, and those using neutrons directly. The main heat application is electricity, but industrial process heat has enormous potential and desalination is already operational. Marine propulsion is an important application of heat from nuclear fission, and space exploration is a small niche application. Neutrons are supplied by research reactors for a variety of uses, most well-known being making radioisotopes for medicine and industry. Radiation from research reactors, synchrotrons and cyclotrons may be used directly for diverse purposes, and that from radioisotopes made in them has immense application in nuclear medicine both for diagnosis and therapy, and in industry. As the hydrogen economy takes shape, nuclear power will have a role in producing it without CO₂ emissions.

18. Micro Reactors for Decentralized Power Sources

Dozens of developers are working on very small modular reactors, referred to here as microreactors, with sizes ranging from 0.5 MWe–50 MWth. At one-20th to one-2000th of the size of a typical light-water reactor under construction globally, these new microreactor concepts offer novel benefits and challenges. Near-term applications include off-grid and islanded micro-grids, such as defense installations, industrial sites, and arctic communities. While these microreactors may appear expensive, they could provide affordable power to off-grid diesel-dependent sites. Unique risks that need to be further studied include how to transport fueled reactor cores, and the security implications of autonomous or minimally staffed nuclear reactors.

As can be seen by the wide range of topics covered, the expectation is that the reader will gain a better appreciation of the contributions that are being made by nuclear energy and the key topics of public concern including nuclear waste disposal, proliferation, sustainability, climate change and the prospects for future nuclear innovations.

Introduction: Images and memory

Civilizations have long memories. The ideas that circulate today, the stories, the pictures, the very words we use have been shaped over generations extending back into prehistory. Much of this is embodied in images, which can be represented in pictures or in words or in primitive concepts that barely reach consciousness. This imagery has a profound effect on our thinking, outweighing rational deliberation more often than we would like to think. Old images weigh with particular force on how people think, and feel, about nuclear energy (Weart, 1988, 2012).

Images associated with nuclear energy do not align strictly with rationality and facts. The familiar Pavlovian association can connect any two things, for example the ringing of a bell with food. The link is often forged by simple repetition. Our brains can also form a durable association from even a single incident when a strong basic emotion such as terror is involved, as may sometimes be seen in post-traumatic stress disorder. This is especially common for disgust, a very ancient mechanism. You may have a lifetime antipathy against something that revolted you on a single memorable occasion. Of course associations are often based on genuine facts. It is sensible for a cat to salivate when it hears the can opener, and if a bird is nauseated after eating a single monarch butterfly it is quite right to avoid similar butterflies in future. But as with Pavlov's dogs, an association can be created by any things that happen to occur together, independent of a meaningful relationship. And once an arbitrary association is entrapped in the sticky web of culture it can become permanent. Thus Christians celebrate the birth of Jesus by gathering around an ever-green tree on December 25th, obedient to associations of new life with greenery and the solstice that are much older than the Bible.

Nuclear energy before Hiroshima

In 1898 Marie and Pierre Curie announced the discovery of radium. The new element emitted radiation that manifested a new form of energy: atomic energy, later called nuclear energy. Other scientists soon declared that atomic energy was not only new but of cosmic import. These atoms had been emitting rays inexhaustibly since the creation of the universe! The press reported the scientists' statements and exaggerated them, yet nothing could seem more sensational than the facts. Then in 1903 Ernest Rutherford and Frederick Soddy announced that the emission of rays by radioactive elements signaled a transformation of one element into another. "Rutherford," Soddy exclaimed at the moment of discovery, "this is transmutation!" Soon everyone within reach of a newspaper was reminded of the notorious goal of alchemists far into the past. Thus radioactivity became bound into an ancient web of images—in fact one of the most ancient and profoundly meaningful webs of associations found in human culture.

Many of the old alchemists had sought to change one chemical element into another, usually lead into gold, but "transmutation" meant more than that. The central goal of alchemy was to create the Philosophers' Stone, which had powers far beyond the transformation of metals. The Stone embodied the deepest secrets of creation. Nothing could be easier than to associate this with radioactivity and atomic energy, for physicists hastened to tell a fascinated public that the new energy manifested in their laboratories was exactly a profound secret of nature. The potential seemed limitless.

When people learn of a new physics discovery the first practical application they look for is usually in medicine, and radioactivity followed the rule. Pierre Curie was the first to report that radium rays (like another recent discovery, X-rays) could cause serious damage to living flesh. This was promptly turned to advantage in attacking some forms of cancer. But journalists, and even some speculative scientists, would not stop there. Might atomic energy, so potent and mysterious, represent a fundamental life-force, the energy of creation itself? The idea had long since been incorporated in ideas about radiation, for since the spread of agriculture if not earlier the brilliant rays of the Sun had been recognized as a basic source of vitality.

This fitted with curious ease into the web of transmutation imagery. The Philosophers' Stone was also the Elixir of Life, the arcane force that could transmute inert dead matter into living things. Turning lead into gold in their crucibles was only a first symbolic step for some of the premodern alchemists. If they could break down matter into its primeval formlessness and recreate it in a perfected condition, so might they renew living flesh. The goal was rebirth and onward to immortality.

In the same tradition, enthusiastic writers of the early 20th century claimed that the magic of radium could not just cure illness but restore youthful vitality. The association of radioactivity with life-force became so widespread that hundreds of entrepreneurs raked in cash by selling patent medicines containing radium or other radioactive materials. You could eat radioactive chocolate and brush your teeth with radioactive toothpaste.

It was not until the 1920s that sensational news accounts reported problems. It turned out that an aging American playboy had swallowed so much radium tonic, in hopes of reviving his flagging sexual powers, that it killed him. Worse, women painting luminous watch dials who pointed the brushes on their lips had fallen prey to “jaw rot,” in fact cancer. Most people continued to view radioactivity positively. Like many things in medicine, it could be dangerous if misused but beneficial in the right hands. Any potent force is a double-edged blade.

If the first application most people look for when they learn of a new physics discovery is medical, the second one is weapons. Science fiction tales that featured “death rays” were already a cliché when Pierre Curie in his 1905 Nobel Prize address warned that “radium could become very dangerous in criminal hands.” Another Nobelist, Soddy, told the public that every grain of matter is a storehouse of stupendously perilous energies. Speculations about atomic explosions followed instantly, although it was not until 1913 that the specific term “atomic bomb” appeared. That was in H.G. Wells’s novel *The World Set Free*, featuring a world war that was—to use a term rapidly becoming associated with atomic energy—apocalyptic.

The Biblical apocalypse, the descent into darkness and chaos followed by a glorious Millenium, is another ancient image associated with the Great Work of the alchemists. Their mystery of transmutating corrupt inert matter into glorious eternal life could also represent a social change. Some mystics dreamed that their secret knowledge could not merely turn lead into gold but bring a Golden Age. In the same vein, Wells’s novel foresaw that after atomic warfare destroyed the world’s cities, a glorious new civilization would rise from the ashes with atomic flying cars and free love. Or could we bypass the danger? Countless newspaper articles, echoing claims by various scientists, exclaimed that science would apply atomic energy to bring global prosperity. The “new alchemists” would create miraculous new materials and supply limitless power.

On the other hand, Soddy warned of the possibility that some careless experimenter might set off an atomic chain reaction that would spread uncontrollably. The horrifying image of an exploded planet joined the associations clustering around radioactivity. There was nothing new in contemplating the end of the world, but the association with atomic energy gave the ultimate apocalypse a worrisome scientific plausibility.

Apocalyptic imagery connected with the deepest roots of the ancient transmutation enterprise. Whether they understood it or not (only some did), the alchemists’ labors in their laboratories involved hopes of personal transformation, call it psychological or spiritual as you will. The Great Work could be a plunge into your darkest places, to embrace sinful urges, overcome them, and emerge reborn. This is also the hero’s journey which, as Joseph Campbell explained, underlies many of the fairy tales and myths and religious writings of every human society. It is a perilous journey. There is a terrifying risk of getting stuck in the midst of the work, descending into chaos and never reborn.

There is much that could be said here about basic emotions and universal childhood experiences and so forth, the sort of thing Freud explored, but we can leave all that aside. However, all that was not left aside by the screenwriters of Hollywood horror movies of the 1930s, some of whom manifestly knew their Freud. A fictional scientist investigating forces could remind the audience (usually unconsciously) of a child who probed forbidden secrets, by implication partly sexual—of course the life-force in penetrating radiation always carried sexual weight. The movie scientist irradiating a pretty actress with his weird ray device could represent not only an overly inquisitive child but at the same time a dangerous and overweening father. Such a dual nature is common; as the anthropologist Claude Levi-Strauss explained, it is the very essence of myths to embrace dualities in a quest to reconcile them. Not by accident did people think “Frankenstein” was the name of the monster as well as the scientist who created it, the child and its father together. Most explicit was *The Invisible Ray* (1936), with Boris Karloff portraying a scientist whose impious experiments with uncanny rays turned the scientist himself into a murderous creature. (He glowed in the dark like a radium watch, and killed people with a touch of his hand.) This was the hero’s rebirth aborted, the seeker of transformation stuck in the darkness, his own wretched victim.

Nothing new here. Standing behind the Hollywood mad scientist was the prideful and damned Dr. Faust. And standing behind the Faust legend (which referenced an actual self-styled magician and alchemist of the 16th century) was a long line of alchemists and wizards tracing their ancestry back to the mages of antiquity. Going still farther back we meet the village witches and tribal shamans found in virtually every human culture, wielding secret spells to heal or harm. And in the shadows behind all of these moves someone very familiar: the parent who dominated our childhood, an overwhelming authority wielding mysterious powers that could be as frightening as they were attractive.

By the late 1930s all this, each and every one of the primitive and potent images described above, could easily come to mind when any member of the public thought for a minute about radioactivity and atomic energy. But the negative aspects of the imagery were peripheral, confined to the adolescent ghettos of pulp science fiction and horror movies. The sober newspapers and magazines aimed at attentive citizens (a small minority, but the makers of opinion and policy) featured mostly optimistic stories. A rising profession of science journalists echoed the scientists they interviewed, describing radioactivity and atomic energy in glowing terms. Medicine was as always the heavyweight in science writing, and new radioactive isotopes and “atom smasher” ray machines were in fact making significant advances. Atomic power plants, not to mention the flying cars Wells had predicted decades earlier, seemed a more distant promise. But when uranium fission was discovered, offering a practical way to release atomic energy, science writers redoubled their claims that a millennial age of plenty was in prospect.

This was 1939. The scientists themselves were thinking about atomic bombs.

Hiroshima and cold war

When the United States announced it had dropped an “atomic bomb” on Hiroshima, everyone knew what that meant. Even before any actual report arrived from the destroyed city, radio announcers spoke portentously of cosmic secrets, apocalyptic perils, golden future prospects—in short, all the things long associated with atomic energy, not excepting Frankenstein’s monster (for the postwar era see [Boyer, 1994](#); [Piehler, 2009](#)).

The first photographs from Hiroshima, censored by American authorities, showed a landscape of endless rubble with no living thing in sight. Atomic reality once again resonated with old imagery. Pictures of abandoned ruins, the desolate remnants of a fallen civilization (Babylon, Rome, Angkor Wat...), had been popular from the 19th century forward. This Empty City was yet another image with transmutational associations, for it could well represent the psychological state of utter loneliness and emptiness at the nadir of the attempt at rebirth.

In the next few years more complete reports and photographs from Hiroshima came to light, and these prodigiously reinforced some particular associations. Shocking stories and gruesome photographs of suffering Japanese drove straight into the regions of the brain where emotions reside. The images evoked horror—that is, a combination of the basic emotions of fear and disgust. The Hiroshima images could not be unseen, permanently associating atomic energy and radiation with pure abhorrence.

The assault on public emotions redoubled in the 1950s when movie-makers discovered a rich vein of public interest in atomic monsters. The pathbreaker was *Godzilla* (1954), a mad scientist’s monster on steroids, awakened by an atomic bomb test. The enormous lizard with radioactive death-ray breath stomping on Tokyo was immediately recognized as a symbol for the atomic bomb. Hollywood responded with *Them!* (1954) featuring ants the size of busses engendered by a bomb test. The movie was successful enough to spawn countless other gigantic monsters, mostly invertebrate. A movie-goer shocked by the sudden onset of a huge, hairy insect would experience pure horror, another blow of the hammer nailing primal emotions onto atomic energy.

Here again atomic science had a hook to attach bizarre associations. Since the 1930s biologists had recognized that radiation can cause genetic mutations. Such tampering with living creatures was immediately felt to carry the deep dangers associated with any transmutation. Mutations mean birth defects, and it is telling that the oldest meaning of “monster” was a malformed birth such as a two-headed calf. The facts of mutation associated radioactivity with yet another primitive image—the defective baby—almost too dreadful to bring to mind.

Yet nothing was as dreadful as the simple fact that on any given day your city could be blasted to smoking rubble. Reports from Hiroshima were quickly outpaced by sober magazine articles portraying a future atomic war, not science-fiction but government-endorsed statements of facts. However awful those might be, fiction went further. The public grew familiar with fantasies of a few lonely survivors roaming among the ruins, an Empty City conveniently stocked with canned food. The survivors might venture into a radioactive Forbidden Zone, the hero’s journey with mutant monsters. Some stories promised the eventual rise of a new and better civilization, the classic apocalyptic transmutation. In other stories apocalypse failed to engender rebirth. An actual end of the world, not as a miracle of divine wrath but from plain human misuse of physics, seemed dreadfully plausible. Hundreds of millions felt tears come to their eyes as they viewed the final scenes of *On the Beach* (1959), the streets of the world’s cities rendered radioactive and emptied of all life.

An actual world war would produce none of these outcomes, but the real possibilities were terrifying enough. Government officials and media editors worked to make everyone aware of the peril, aiming to promote civil defense. With Hiroshima-sized bombs it seemed sensible to adopt the measures that Europeans had recently used as their cities were pulverized. Authorities took care to present images that would prompt effective preparation, images accurate enough to “inoculate” the public so they would not panic in an attack, but not images so graphic that citizens would recoil in horror, outrage, or despair. Yet no amount of care could make palatable the dreadful prospect: hundreds of ruined cities populated by millions of corpses. (Hardly anyone dared to recognize that tens of millions more would be refugees, diseased and starving in squalid camps or wandering on their own.) The most emotionally vulnerable citizens, of course, were children. “Duck and cover” school exercises and instructions on how to escape radioactive poisons gave an entire generation nightmares—and a growing skepticism that authorities could be trusted to protect them.

Adult citizens too were beginning to feel misgivings about the authorities who controlled the fearsome new power, as represented primarily by the US Atomic Energy Commission (AEC). The first questions arose following widely publicized bomb tests in the Nevada desert. The radioactive dust from the mushroom clouds was easily detected when it fell to earth hundreds or even thousands of miles away. The obvious association was the “black rain” following the Hiroshima and Nagasaki bombs, fallout that many survivors believed irretrievably contaminated them and perhaps their progeny as well. AEC spokesmen insisted that everything was fine, and most Americans patriotically accepted that the tests were necessary to prevail in the Cold War. But doubts lingered, well-founded doubts as later investigations revealed, that the officials had been over-confident about the risks if not deliberately disingenuous.

To excuse their bland and elliptical reassurances the AEC pled the necessities of Cold War secrecy. Almost anything related to atomic energy was treated as a mysterious magic, more potent and perilous than any other secret in the public mind—and even in American law, which enacted a death penalty specifically for atomic espionage. The public of the 1950s was obsessed with atomic secrets, for here too facts aligned all too well with myths. Communist spies both real and fictional took up the mantle of the 1930s mad scientists who might blow up the world. By ancient tradition and deep in the psychology of childhood, anyone with powerful secrets seemed threatening. Critics remarked that the AEC with its secrets had adopted a “father knows best” attitude that was not always reassuring.

These feelings broke into the open in 1954 when a test of a hydrogen fusion device in mid-Pacific was three times more powerful than calculated, projecting clouds of intensely radioactive dust hundreds of miles across the ocean. Distant islanders were struck with radiation illness, and the crew of a Japanese fishing vessel, the misnamed *Lucky Dragon*, required urgent medical care. When the AEC claimed that everything was safe (details withheld for national security), nothing to see here folks, many people recognized the statements were misleading and some saw outright dishonesty.

By 1960 the number of hydrogen bombs was rapidly climbing, each three orders of magnitude more powerful than a fission bomb. Cowering under a desk would not save you if you were *inside* the fireball. If you were not directly incinerated you could face highly radioactive residues scattered across the countryside; your only recourse would be to hide underground for weeks. A rage for building fallout shelters swept the United States in the early 1960s. The media featured anguished debates about whether you should shoot neighbors who tried to get in. And if you did survive, what would you find when you crept out? The fallout-shelter movement collapsed in futility as the number of hydrogen bomb warheads climbed into the thousands, but it had powerfully reinforced associations between atomic energy and images of post-apocalyptic savagery and desolation.

To many citizens it seemed plain insanity that national authorities were building enough ballistic warheads to truly shatter civilization. The mad scientist (exemplified by the physicist “father” of the hydrogen bomb, Edward Teller) became allied in public imagery with another trope of long standing, the bloody-minded military leader (exemplified by the actual commander of the American strategic forces, General Curtis LeMay, who had incinerated a million residents of Tokyo in a single night and planned to repeat the performance on Moscow). The mad scientist/general was connected in turn with another traditional villain, the warmongering government leader (exemplified by your enemy of choice, be it a Communist tyrant or the fervently anti-Communist 1964 Republican Presidential candidate, Barry Goldwater). Here was another dense tangle of imagery, immortalized in the characters of the 1964 movie *Dr. Strangelove*. Apparently such men had to be stopped before they stumbled into World War III and destroyed everything.

A public movement against nuclear weapons had begun in Japan in the wake of the *Lucky Dragon* affair, reinforced by reports that some tuna caught in the Pacific Ocean were radioactive. The Japanese reaction was similar to what Americans would feel if they heard their hamburgers were polluted. Opposition to the arms race rapidly spread around the world, bringing millions out in mass demonstrations. Originating in a reaction to bomb test fallout, the movement gave most of its attention to this “death dust.” Fallout was potent as a “backyard” issue, for sensitive geiger counters could detect traces of radioactivity thousands of miles downwind from a test. Every mother could worry that her child was eating contaminated food.

The movement’s ultimate goal was to ban the bombs altogether, but leaders understood that taking on the entire Cold War was impracticable. They concentrated on demanding a ban on weapon tests. Halting the development of even worse devices was sensible in itself, and could be a first step toward international détente.

The history of the vast “ban-the-bomb” movement has filled entire books (Wittner, 1993-2003) and this essay will restrict itself to one point. Through every medium from songs to mass demonstrations the movement pounded into the public mind one message: radioactivity, even the minuscule amount that might taint a snowfall 10,000 miles distant from a bomb test, was horrible above all horrors. Nobel-prize scientists exclaimed that exposing billions of people to billionths of a dose would strike down millions with cancer, while millions of babies would suffer mutational defects.

These were unprovable claims, since even a million cancers or birth defects would be an undetectably small addition to these great burdens on humanity. Other scientists insisted that our bodies are well adapted to radiation at the level found in nature from cosmic rays and rocks, a level which global fallout increased by only a tiny fraction. Some went on to argue, like the believers in healthful rays who were still patronizing spas that advertised radium water, that a bit of radiation stimulates the body’s repair mechanisms. Perhaps so; the science remains uncertain and contentious to the present day. For many experts and the bulk of the public, the argument that prevailed was that a little additional radiation might possibly bring mass death, best to take no chances. Doctors began to observe that if most people were grateful for therapies with X-rays and radioactive materials (which every year preserved millions of lives), a significant minority recoiled from anything that involved the slightest trace of radiation. Nobody asserted that fallout could actually bring the end of the world... and then *On the Beach* did assert it. The arguments continued for years in every public venue until many people came to see all radioactivity—a basic feature of the physical world—as an unrelieved evil.

Underlying these ideas was a threat that even the most ancient and primitive organisms know and shun: pollution. The response to a poison in the environment is disgust, fear, and eventually horror. A tight connection between radioactivity and pollution had emerged in reports about the Hiroshima survivors who believed that simply being in the vicinity of the blast had contaminated them for life. But it was the movement against nuclear weapons that solidified the association as a basic component of modern culture.

Disgust is not only a physical but a social phenomenon. Brain scans find that regions activated by a mention of, say, excrement, are also activated by “disgusting” behavior, for example a description of someone who molested little boys. It appears that human evolution hijacked an ancient physiological defense for use in social situations. When we say, “that was a shitty thing to do” we are invoking something very deep. Thus there was a fundamental connection between the opposition to bomb test fallout and distrust of the authorities responsible for it. Such distrust was indeed central in the movement’s politics.

The pressure on governments became too strong to withstand. After the 1963 Cuban Missile Crisis brought a spike of unbearable terror, the Cold War protagonists undertook negotiations. The result was an agreement to restrict bomb tests to underground explosions. That had no practical effect on the arms race, but it meant there would be no more fallout drifting into people’s backyards. The agreement robbed the anti-bomb movement of its central argument, and also reassured the public as a small step away from obdurate hostility. The movement collapsed. Not only mass demonstrations but newspaper articles, books, movies, cartoons, every

sort of production about nuclear war, which had all proliferated after 1945 and became even more numerous in the early 1960s, abruptly disappeared from the public stage. People who were asked in the early 1960s to list their main concerns usually put nuclear war at or near the top; asked in the 1970s, few brought it up at all. Since nations were as prepared as ever to launch their missiles at a moment's notice, this looks like a case of classic denial. In the psychology of an individual, denial happens when something is so disturbing that it never rises to conscious thought. After 1964 this appears to have become a mass phenomenon.

Nuclear reactors

For all the bomb terrors, through the 1950s and 1960s the public was enthusiastic about employing "Our Friend the Atom" (the title of a widely seen Disney television episode and educational film). Scientists since the Curies had staked their hopes and careers on using the new energy for the benefit of humanity, and the onus of building weapons only redoubled their efforts. The scientists' well-publicized enthusiasm was seconded by government action. To counter the public distrust aroused by the threat of nuclear war, and to score Cold War points by promoting peace and prosperity, the US Atomic Energy Commission and its counterparts abroad launched extensive education and propaganda campaigns. "Atoms for Peace" was both a rallying cry and a justification for serious research and development work.

Experts, journalists, politicians, corporate and government officials, opinion leaders of every stripe repeated the ambitious claims made ever since the discovery of radioactivity. The magic of the atom would bring astounding new materials, incredible benefits to medicine and agriculture, and not least, a limitless source of cheap power. If personal flying atomic cars posed difficulties, engineers set to work designing atomic aircraft, and atomic ships were actually built (starting with submarines on the military budget, but peaceful ones too). Most significant of all was the development and deployment of full-scale atomic power plants, nuclear reactors generating electricity. Government support and the enthusiasm of a handful of corporate executives culminated in 1957 when, to universal acclaim, the first large and entirely "peaceful" reactor started feeding power into the electrical grid.

It might be a business project but it still seemed like magic. Physicists themselves continued to tout atomic energy as the cosmic force that powered the universe, a mystery just short of the Philosophers' Stone. Few admitted that the forces driving radioactivity are no more, and no less, wondrous than familiar electrochemical forces; operating a reactor is metaphysically equivalent to burning wood. But nothing could loosen the association of atomic energy in general and radioactivity in particular with uncanny secrets and powers. Anything so potent could be terrifying if mishandled. Were the authorities trustworthy?

The "anti-nuclear movement" of the early 1960s, which is to say the anti-nuclear-bomb movement, had not entirely dissolved. In the late 1960s many of the leaders and organizations that had campaigned against bomb tests began to incubate a new "anti-nuclear movement" that opposed building power plants. In the 1970s crowds again chanted "No nukes!" but now referring to reactors rather than bombs. Not only the language but the technical arguments had scarcely changed. It was again a backyard issue, as communities in the vicinity of a planned reactor recoiled at the thought that an accident or even routine emissions could contaminate them with radioactive materials. You didn't have to live downwind from a reactor to worry, as nuclear materials and particularly radioactive waste traveled the rails and the highways. Once again experts debated fruitlessly whether exposing a large population to minuscule amounts of radiation was virtually harmless or virtually genocidal. Of course the actual genocidal threat was the proliferation of hydrogen bombs, mounting relentlessly into the tens of thousands, but that was rarely mentioned. Denial persisted through the 1970s.

Denial is often accompanied by displacement. Displacement can be entirely conscious, as when a monk turns from lascivious thoughts to contemplating the Virgin. Often it is unconscious. The classic example is a monkey who, attacked and defeated by a monkey of higher status, turns and attacks one below him (much the same has been observed in schoolyards and offices). The deepest motivation of the anti-reactor movement may well have included displacement of the dread of bombs onto something quite different.

The movement also redeployed the growing distrust of authorities. Originally provoked by bomb test fallout and the spread of apocalyptic weapons, distrust escalated with the coming of age of the postwar "baby boom" generation. This was a generation mobilized not only by their experience of civil defense delusions and the perilous Cold War standoff but equally by fierce struggles for civil rights in the American South, the Vietnam War, and many other issues (European students were particularly outraged by the persistent residues of fascism and their own hidebound university authorities).

The scientists who devised bombs and the generals and political leaders who threatened to use them now shared the stigma of villainy with executives of the rising nuclear industry, and onward to capitalists in general. It was no big stretch, for corporate bosses had been attacked for a century in everything from muckraking books to cartoons. The movement used its tactics of mass demonstrations and civil disobedience and media messaging, developed to oppose weapons, not only to block new reactors but to assail the entire military-scientific-government-corporate "establishment."

The movement opposing reactors, like the atom-bomb movement a decade earlier, has a history spanning countless significant actions of many kinds in many countries; this essay will restrict itself to one point. Through every medium from lawsuits to songs to invasions of reactor sites, the movement pounded into the public mind the message that reactors were as horrible as bombs.

After all, couldn't an atomic power plant explode like the Hiroshima bomb? The public watched closely as the industry struggled with the threat of accidents. Reactor experts were at the forefront in demanding strict safety measures—and in dreaming up the worst possible disaster scenarios, however unlikely, in order to figure out how to prevent them. To be sure, it is physically impossible for a reactor to blow up like an atomic bomb, since a runaway reaction would simply melt the fuel. The experts calculated, however,

that during a meltdown a simple steam explosion could release a cloud of radioactive material. As usual, the facts resonated with apocalyptic fears. Opponents of reactors, drawing on the familiar scenarios of hydrogen-bomb warfare, exclaimed that fallout from a reactor accident could kill countless citizens and render entire states uninhabitable.

Some of the most effective arguments looked at radioactive waste. The very word “waste,” described as coming from the “back end” of the fuel cycle, evoked disgusting pollution, something so awful it had to be hidden away. The experts themselves took it for granted that they must take extraordinary measures to isolate radioactive materials. Most passionately reviled was plutonium, the very stuff of bombs; with its radioactive half-life of 24,000 years it seemed to imperil all posterity. Few remarked that if even the tiniest trace of a carcinogen like plutonium really was dangerous, then over future generations the waste from coal-burning plants posed a far greater danger. The carcinogen and mutagen arsenic, for example, concentrates in coal ash, and as an element its lifetime is infinite. While the thousands of tons of reactor waste were locked up in costly containers, the millions of tons of coal waste were piled up in open-air sludge dumps. (Nor are solar panels innocent, junked after a few decades with their burden of the carcinogenic element cadmium.) The public knew nothing of this. It was radioactive materials that inspired awe and horror.

The growing nuclear industry and its government supporters fought their opponents with information and public relations exercises. For example, it was unfortunate that the first thing people thought of when they heard the word “atom” was “bomb.” So in the 1960s experts deliberately changed their language to “nuclear,” e.g., replacing “atomic power” with “nuclear power.” After all, the energy arises from changes in the nucleus rather than in the atom as a whole. But it took only a few years for all the negative associations to glue themselves firmly onto anything “nuclear,” beginning with “nuclear weapons.” Doctors who prescribed Nuclear Magnetic Resonance Imaging began to omit the first word to avoid repelling patients.

The advocates for nuclear energy mostly had roots in engineering, science, and corporate or government bureaucracy; their native language was facts and rational argument. Many held what was later called the “deficit model” of public opinion: people were ignorant, just give them the facts and all would be well. The films, advertisements, museum exhibits, and so forth that industry and government deployed were reasonable and somewhat effective, but many of the efforts were factual and dry, devolving into exhaustive technical reports.

Most of the opponents of reactors came from the liberal arts. They made expert use of every medium from clever posters to full-scale Hollywood movies, rarely paying scrupulous attention to facts. In a battle of vivid imagery against statistics the advantage lies with imagery.

Social scientists were barely beginning the studies that would demonstrate that facts play a minor role in public opinion. Experiments eventually showed that once people have adopted an opinion they hold to it tightly. Confronted with contrary facts, people will invent counter-arguments, or mis-hear the uncomfortable facts, or simply forget them. To be sure, a curious and fair-minded citizen can be swayed by a sound argument. But many other things are no less potent. Your identification with a social group—your neighbors, your favorite media, the political leaders and other celebrities you admire—this tends to align your opinions. In particular an idea is most easily accepted if it fits with your political ideology. It should also fit with your gut feelings about such matters as the trustworthiness of officials, how important it is to avoid anything risky, whether natural resources ought to be used or protected.

Underlying all attitudes are features in the way evolution shaped human brains (Kahneman et al., 1982; Slovic, 2010). Mechanisms that efficiently warn us of a lion hiding in the grass are less useful in an industrial civilization. Instinctively we feel that something invisible (like nuclear radiation) is more dreadful than something visible (like sunlight, the cause of countless skin cancers). A novel risk (nuclear waste) generates more murky anxiety than a familiar risk however deadly (tobacco smoke). An unusual and spectacular risk (airplane crashes) gets far more attention from the media and the public than an everyday risk with far worse mortality statistics (car crashes). A risk that seems to be imposed by an outside authority (nuclear waste again) provokes greater dismay than a risk people imagine they undertake voluntarily (tobacco again). And of course a risk that for decades has been intimately associated with uncanny secrets, and insidious pollution, and horrifying monsters, and their overweening masters, not to mention blasted cities and the end of the world...

As usual some realities of nuclear energy resonated with the worries. The infant industry naturally made mistakes. If opponents exaggerated every problem, some officials reinforced distrust by covering up difficulties and imperiously scoffing at criticism as ignorant and regressive. Wastes in particular were a magnet for actual problems as well as visceral anxieties. To give only one example, in 1971 the AEC announced that it would solve the problem by burying wastes in a Kansas salt dome, since salt deposits are naturally self-healing. Shortly it appeared that the dome had been drilled extensively for brine. The AEC had picked a remarkable rarity, a wet and leaky salt dome. The agency retreated amid great embarrassment, setting the tone for an endless dispiriting saga of geological and political feuding over waste disposal.

The AEC officials' unbridled enthusiasm for nuclear energy had long raised doubts that they could be trusted to regulate their own creations. In 1975 Congress responded by splitting the agency. Development and promotion of reactors were entrusted to a new Energy Research and Development Administration (later the Department of Energy), while a new Nuclear Regulatory Commission would serve as a strict independent watchdog. Meanwhile the nuclear industry, learning from its mistakes, devoted resources to studying public opinion and developing sound communication practices. Executives and government officials gradually weaned themselves from the authoritative “father knows best” attitude of the early AEC. Their efforts were especially effective in the neighborhood of reactors, where citizens could have personal interactions with their engineer neighbors and could inspect the plants themselves. Eventually almost the only places where a new reactor could be planned without provoking vehement opposition were sites where reactors were already running (Bisconti, 2021). But for the public at large the damage had already been done. Opinions and associations formed over decades and sealed with powerful emotions at the height of the Cold War were not to be lightly overturned.

The public's distrust redoubled in 1979 when a partial meltdown wrecked a reactor at Three Mile Island, Pennsylvania. Weeks of sensational news reports panicked people for thousands of miles around before authorities could confirm that only inconsequential traces of radioactive material had escaped. Faith in the nuclear industry had scarcely recovered by 1986 when a reactor exploded at Chernobyl in Ukraine. That did contaminate a wide region, creating another resonance of fact with myth: an actual empty city, an actual forbidden radioactive death zone. The accident directly killed a few dozen workers and probably caused a barely visible increase in cancer rates among the nearby populace. But the main cause of morbidity and mortality lay elsewhere: in dread of nuclear radiation. A mass evacuation swept up more than a hundred thousand people. Displaced from their communities and their livelihoods, tormented by a suspicion that they were irrevocably contaminated by radioactivity, tens of thousands fell prey to poverty, chronic depression, alcoholism, and even suicide (not to mention uncounted abortions by women who thought their infants might be deformed).

The lesson was overlooked in 2011 when a great tsunami caused massive reactor failures at Fukushima, Japan. The radioactive materials that escaped caused no direct fatalities but might bring a few hundred future cancer deaths. Far more important was a mandatory evacuation that displaced more than a hundred thousand people from mildly contaminated regions, in the process killing more than 2000 of them (for example, hospital patients). The refugees experienced much the same miseries as their Ukrainian counterparts; most would suffer far more over their lifetimes than if they had remained in their homes, even if there was a slight increase in the cancer risk (Oughton, 2016). Yet the evacuation was not the largest cause of illness and death. Distrust of the nuclear industry was now so powerful that Germany and Japan quickly shut down many of their reactors, some of them never to restart. Over the following decade, air pollution from the fossil fuel plants that took the place of the reactors would inflict an estimated 30,000 premature deaths (Kharecha and Sato, 2019). Nuclear fear can be deadly.

Nuclear imagery in the 21st century

Civilizations have long memories, but images fade unless they are renewed. Hardly anyone born after the Chernobyl disaster experienced the shock, disgust, and dread raised by the events and images familiar to their elders. To be sure, all the old atomic war and monster movies were available. Many youngsters watched them on the television show *Mystery Science Theater 3000* ("MST3k," 1988–99, now available on Netflix), where wisecracks by a fictional audience subverted the black-and-white action. This was the realm of the postmodern. The postmodern attitude takes up images and ideas from the past without taking them seriously, it throws about references with a wink, it sells a world-weary irony. These lurching monsters might have terrified your parents, but their power was spent (Weart, 2012).

When the television comedy *The Simpsons* (1989–) based its opening sequence on a dangerously inept nuclear reactor operator, and played episodes featuring the greedy owner of the reactors or perhaps a three-eyed mutant fish, it took for granted that the audience would understand its references—and be amused. Referencing was equally plain in another production enormously popular among young people, the video game series *Fallout*. The player wanders in a post-apocalyptic city reduced to radioactive rubble and combats mutant monsters, but unlike the monsters of the 1950s productions, these are not imagined to represent anything more real than the dragons and witches of other video games. With postmodern detachment you might get less of a visceral shock than the 1950s productions bestowed. But there is also less actual thinking involved: the sly references do not ask to be questioned. The power of the entire tangle of transmutational imagery did not go away when the mad scientist became a cartoon figure of fun. The emotional associations linger underground in the unconscious realms where they had dwelt for generations.

That was not all that remains out of sight and out of mind. Nations still deploy more than 3000 nuclear warheads that can be launched on a few minutes' notice. The President of the United States and the President of Russia each holds the unchallenged power to launch their share and destroy civilization: nobody is in a position to stop them. These facts are hardly ever discussed, a striking persistence of denial through half a century. (We can leave aside a brief but intense revival of war fears in 1980–83 when the bellicose President Ronald Reagan confronted a hidebound and decaying Soviet regime.) In classic denial, what is repressed is never really gone. It is reasonable to suppose that anything having to do with nuclear energy has strings that tie it to deeply buried terrors, transmitting an influence all the more powerful for being unacknowledged.

In the absence of war, historical events pulled up other old associations. Terrorist attacks on November 9, 2001 froze Americans in front of their televisions for a week, obsessively watching the World Trade Center collapse again and again. The event marked a generation much as Hiroshima had marked their elders, traumatic less for what had happened than for what it threatened about the future. The cloud that rose over New York City was widely described as a mushroom cloud, a phrase that had long been a metonym for an atomic blast. Without conscious decision the site came to be called "ground zero," a phrase invented in 1945 by scientists describing the effects of an atomic bomb explosion. A thought came simultaneously to many: what if terrorists set off a nuclear device?

The idea had a history reaching back through the Communist spies and infiltrators of the 1950s to the mad atomic scientists of the 1930s and beyond. Terrorists had already set off portable atomic bombs in a 1908 novel (Anatole France's *Penguin Island*), following still earlier stories of evil chemists devising novel explosives. In a popular variation the evildoer was the ruler of a powerful corporation, well-funded conspiracy, gang, or entire nation, a trope featured in so many James Bond movies (*Dr. No*, 1962, *et seq.*) that another successful movie series was based on a parody. "Let's just do what we always do," declared Dr. Evil, "hi-jack some nuclear weapons and hold the world hostage" (*Austin Powers: International Man of Mystery*, 1997). You couldn't get more post-modern than that, an ironic reference to the James Bond villain who was himself an ironic reference to earlier villainous rulers

wielding terrible secret weapons. Returning to the real world, any dictator who might get hold of a nuclear weapon was feared not only because he might use it himself, but because he might let it fall into the hands of terrorists.

These venerable fears were prominent in the actual history of early 21st century international relations. The American invasion of Iraq in 2003, the repeated war scares involving Iran or North Korea—each of these conflicts revolved around potential possession of nuclear weapons. The public feared and despised the rulers of these states as if they were traditional mad-science villains.

As for the nuclear power industry, when experts discussed reactors their greatest worry was proliferation of weapons. Reactors cannot produce power without manufacturing plutonium, the stuff of bombs, and the isotope uranium-235 is excellent for both reactors and weapons. Was it wise to encourage almost any nation to build reactors? Below the national level, while no terrorist organization seemed capable of crafting a Hiroshima-style bomb, if they simply stole some radioactive material and spread it around a city they would cause devastating panic. To be sure, there are many more noxious materials that are far easier to obtain, but only radioactive stuff would rouse apocalyptic dread.

To the public, unlike the experts, terrorism was not the most worrisome thing about reactors. Now as for half a century the public's first concern was bomb-like explosions and fallout as at Chernobyl and Fukushima. To address reactor safety the nuclear industry in the United States had developed a new system after the shock of the Three Mile Island accident. Executives had believed themselves free from responsibility so long as they satisfied the mountains of paperwork rules set by the Nuclear Regulatory Commission, but that had proved inadequate. From the 1980s onward the industry developed an independent program of self-criticism and rigorous inspections. If the industry's own engineers determined that a company's procedures were lax, the people responsible could be fired. Comparable systems were urged on the Russians, Japanese, and others (and might have prevented the Chernobyl and Fukushima disasters), but adoption was slow.

The public's second concern was radioactive waste. By now the technical problems of sequestering materials were essentially solved; the real problems were political. The anti-nuclear movement had faded away in the 1980s as nations stopped building reactors in any location where they could meet serious public opposition (thus no new reactors in the United States, but many in China). Time and the passing of Cold War stresses had dimmed nuclear fear among the public at large; only a tenth clung to powerful anti-nuclear convictions (Bisconti, 2021). But in political systems like the United States that offered many points where opposition could be raised, a passionate minority could block a political solution. The anti-nuclear impetus was only dormant and any appropriate stimulus could revive it. Nothing roused the opponents so much as anything involving radioactive materials, such as proposals for the disposal of wastes.

The 21st century public was highly sensitive to pollution in any form. Tobacco smoke, lead in paint or gasoline, DDT and other pesticides, oil spills in the oceans, and much else had turned out to be far more harmful than corporations and their tame scientists had claimed. Purity was the new watchword. Movements even arose to oppose substances that scientists fully endorsed, from genetically modified organisms to measles vaccine. Mr. Burns, the evil proprietor of the nuclear reactors in *The Simpsons*, could have been a representative of any of a dozen distrusted industries—although the creators of the series had chosen the nuclear industry as iconic.

The future: Debating climate and nuclear power

In the 21st century the public became increasingly concerned about another type of pollution: greenhouse gases. Global warming, like nuclear war, posed a novel and existential threat to world civilization.

Global warming had no resonances with ancient psychological and social themes. The mascot for the issue was the endangered polar bear, and not everyone cared much about this ferocious man-eater. Imagery of collapsing glaciers and ruined coral reefs were likewise remote from the back yard. Climate change looked far away not only in space but in time. Economic and political plans that could barely see 5 years ahead refused to worry about the next generation (Weart, 2008, 2019).

Public concern awakened in the 2010s in reaction to a manifest increase in the worst weather disasters—heat waves, droughts, wildfires, floods, hurricanes—and unequivocal statements by all reputable experts that our emissions were to blame. As early as the 1970s some advocates of nuclear power had mentioned the prospect of global warming as one among many arguments for promoting reactors. Now some citizens, including respected environmentalists who had once opposed nuclear power, recognized it as a lesser danger. Evidence mounted that climate change is a threat so dire that taking every conceivable measure to replace fossil fuels might barely be enough.

When climate scientists had first addressed the public they followed the deficit model of public opinion, like nuclear engineers and their allies during the first decades of reactor development. The scientists devoted countless hours to crafting reports by national academies and scientific societies, followed by entire years compiling evidence for the Intergovernmental Panel on Climate Change. Their success was modest. Explanations and facts are insufficient to sell an idea that conflicts with cherished ideologies, to say nothing of the colossal fossil fuel industries. Coal and oil interests had lobbied quietly against nuclear power ever since the 1950s, and starting in the late 1980s they spent billions of dollars on climate lobbying, misinformation, and obfuscation.

Advocates of action against climate change gradually discovered the immense existing literature on communication, the studies of everything from commercial advertising to public health campaigns. Scholars pressed on to develop a focused academic “climate communication science” that went well beyond the sort of opinion and attitude studies that the nuclear industry had conducted over the years. The advocates even wrote handbooks and maintained websites for climate debaters and schoolteachers (Boykoff, 2019; Cook, 2019; Cook and Lewandowsky, 2011; Moser, 2009, 2016; Shepardson et al., 2017). Although the studies were subject to the uncertainties of all social science and psychology, researchers offered some reasonably reliable guidelines.

Nothing is more important for an advocate, they explained, than to come to the audience without preconceptions, as eager to listen as to talk. “Believe me because I am an expert” had already in the 1960s turned many against the nuclear establishment. The messenger needs to seek out common ground with the audience’s goals, meeting them where they can feel comfortable. There are indications, for example, that liberals can be swayed by appeals to their empathy with the global poor, whereas conservatives may respond better to arguments involving jobs and the national interest. An issue should thus be “framed” in terms appropriate to the audience. Framing the next generation of reactors as marvels of engineering prowess could work well for some audiences, but boasts of mastering the forces of nature could also call up masculine associations reaching back to the mad scientist. That could alienate, for example, women who would respond better to reactors framed as a technology valuable for preserving the global environment.

Framing begins with the choice of the messenger, preferably someone clearly sympathetic to the listeners’ ideological orientation. A Republican member of an evangelical church will get much farther with that particular audience than an agnostic Democrat, regardless of what arguments they deploy. As the nuclear industry learned long ago, nothing is so effective as neighbor talking to neighbor. Also useful, when applicable, is explaining that a belief is more popular than the audience imagines, for humans want to belong. Most Americans, for example, are surprised to learn that nearly all climate scientists agree that emissions are dangerously warming the planet (by the 2010s the few dissenters were no longer publishing in peer-reviewed journals, but they continued to attract attention thanks to ample funding and political connections). Similarly, barely half of Americans know that a solid majority of their fellow citizens accept nuclear reactors as part of the electrical power system. Experiments have found that giving people such information about their peers can change their attitude.

As noted earlier, factual information about the issue itself gives surprisingly little help in winning people to a viewpoint (and technical or scientific information least of all). Facts and logic are certainly important and it is essential to lay them out. But they need to be embedded in a humanly appealing story.

A messenger may need to confront specific objections, based as often on misinformation as on facts. Arguing is risky: when people hear, “vaccination does not cause autism,” a week later what might come to their mind is, “there is some kind of connection between vaccination and autism.” And as anyone who has argued politics with a relative knows, confrontation often just makes your interlocutor dig in with redoubled conviction. A wise messenger will begin with a positive statement that addresses concerns you share with your audience (“vaccination can save your child’s life”) to frame the issue before proceeding to attack opposing arguments.

Framing should include a choice of rhetorical style appropriate to the occasion (dramatic? informational? inspirational?). Every technical field has its own specialized language which can mean something quite different to the lay public. Climate scientists, for example, must beware that when they speak of positive feedback (such as a warmer tundra emitting more greenhouse gases that cause more warming), a listener may think “positive” means “good.” Radiation “exposure” even at the most innocuous level sounds frightening; “contamination” of water by a single atom may be perceived as disgusting. It is even more important to think about what a pictorial image may suggest. The countless published photographs of a cavernous space with a vast pool of water full of spent reactor fuel, glowing with an eerie blue light, are not necessarily reassuring. Logic itself can have an unexpected meaning. Nuclear experts often contrast the tiny amount of radiation that might leak from a reactor to the much larger amounts of natural radiation from cosmic rays or even from bananas. But for some people anything “natural” is acceptable while anything artificially imposed is suspect (Bisconti Research Inc., 2019; Bisconti, 2021).

With distrust of authorities central to the psychology of opposition, it helps to empower the public as far as possible. Some of this can be channeled through standard democratic government mechanisms; the law courts and the Nuclear Regulatory Commission have largely retained the public’s trust to represent their concerns. More directly empowering are offering frank dialogs between industrial and public representatives, and giving the local community a meaningful role in radiation monitoring, evacuation planning, and the like.

None of these methods can prevail in the long run unless your argument is factually valid. The nuclear industry will not be fully accepted until it can provide convincing evidence that it will handle reactor safety and wastes more reliably than in the past. And of course the industry must show that it can compete economically with power provided by renewable sources plus energy storage. People can be remarkably flexible when they expect to save money. Nothing could improve public acceptance so much as the advances in reactor design described elsewhere in this volume, which demonstrably make disasters all but impossible (Rothwell, 2021a; Ingersoll, 2021; Greneche, 2021), and the economic efficiencies of scale resulting from mass deployment such as some countries are undertaking today (Rothwell, 2021b).

One thing is certain: the facts about climate change will become increasingly obvious and increasingly grim. Year by year disasters are happening more often and with greater damage, just as scientists predicted for decades. The pain is only beginning with much worse to come. It becomes obvious that every available technology must be pressed into service. However great the public’s fears of nuclear energy and radiation, the catastrophic costs and personal distress from climate disruption must eventually push them aside.

Public opinion in action

Between 1976 and 1992, antinuclear activists sponsored 21 ballot initiatives in 11 US states aimed at banning the construction of nuclear power plants or shutting down existing nuclear power plants. The votes on these initiatives provided an unequivocal test of public opinion. In all but one case, the antinuclear effort failed and the public voted in favor of the plants. Why? With all the dramatic imagery linked to nuclear power and the fear this imagery can evoke (Weart 2021), the results of these ballot initiatives must have come as a surprise.

Also surprising must have been the first time a nuclear power plant received regulatory approval to extend its operating license by 20 years (subject to continuing regulatory review)—with little, if any, opposition. License renewals for another 90 nuclear power plants followed smoothly.

In fact, a 36-year program of research shows that the majority of the US public favors nuclear energy, and this support is even stronger among nuclear power plant neighbors. This article draws primarily from that extensive and in-depth program of research on public attitudes toward nuclear energy by Bisconti Research.¹

Favorability trends

Bisconti Research has tracked public opinion on some questions at least annually since 1983. The surveys used nationally representative samples of at least 1,000, with a margin of error of plus or minus three percentage points.

In 2019, 61% of the US public said they favored “the use of nuclear energy as one of the ways to provide electricity in the United States.” The national survey findings for 2018 were practically identical (see Findings 1).

The long-term trends show that support for nuclear energy is much greater today than it was when the survey program began in 1983 (Findings 2).

In 1983, the public was equally divided between those in favor of nuclear energy and those opposed. In 2019, those who favored nuclear energy outnumbered those who opposed by 61% to 26%; 13% had no opinion. There have been some downturns—most notably after the accident at Chernobyl in 1986 and the tsunami at Fukushima in 2011. Upturns coincided with periods of perceived need for energy. Those in favor peaked in 2010, as the industry geared up for a nuclear renaissance and the Democrats in power (historically unlikely allies) began to see the environmental benefits of this clean-air, carbon-free energy. The Fukushima accident the next year put a damper on this new enthusiasm.

Over the years, open-ended questions asking reasons for respondents’ opinions of nuclear energy have found that accidents are the main concern people have, and, therefore, real accidents like Chernobyl and Fukushima reinforce this concern. That is especially true when the media coverage shows images of devastation or human tragedy. In the case of Fukushima, images of devastation from the earthquake and tsunami could easily have been associated with the accident at the nuclear power plant that was caused by the tsunami. As of 2015, top reasons mentioned by those who *favored* nuclear energy were:

- Need the energy (13%)
- Environment, clean, less air pollution (10%)

¹Dr. Ann Stouffer Bisconti initiated the research program in 1983 at the Nuclear Energy Institute (NEI) and its predecessor, the US Council for Energy Awareness (USCEA). Bisconti Research, Inc. continues the program with various sponsors, through the present day. For the past 15 years, the fieldwork of all surveys has been by Quest Global Research.

Overall, do you *strongly favor*, *somewhat favor*, *somewhat oppose*, or *strongly oppose* the use of nuclear energy as one of the ways to provide electricity in the United States? (%)

Findings 1 Favorability to nuclear energy steady (General US Public, 2018 and 2019).

Overall, do you *strongly favor*, *somewhat favor*, *somewhat oppose*, or *strongly oppose* the use of nuclear energy as one of the ways to provide electricity in the United States? (%)

Findings 2 Favorability to nuclear energy increased over long term (General US Public, Annual Averages).

- Low cost (8%)
- Others: safe, reliable, efficient, good alternative

The top reasons that came to mind by those *opposed* to nuclear energy were:

- Danger, accidents (49%)
- Waste (10%)
- Others: prefer other sources, not needed, scary

Two points jump out from these numbers:

- First, favorable attitudes are less focused than unfavorable attitudes. There is no single favorable attribute such as clean air energy that stands out. The attributes are diffuse and fuzzy. That indicates a need to focus more clearly on how nuclear energy benefits humanity.
- Second, among reasons to oppose nuclear energy, accidents are the main concern, far more than waste. However, waste does become a concern once it is raised, and some policymakers view waste as an obstacle.

One of the difficulties in communicating about nuclear waste is that people hold an image of spent fuel as a liquid that is uncontrolled. Words alone are not sufficient to convey that spent nuclear fuel is solid, compact, and contained. For this reason, advocates find that actual models, such as a simulated fuel pellet accompanied by photos of the many layers of containment are helpful. Some advocates use props such as a Coke can to convey the amount of spent fuel that would be created by a family of four over a lifetime of using only nuclear energy for electricity.

Gender continues to be associated with attitudes toward nuclear energy (**Findings 3**). Among the general public surveyed in 2019, more men (69%) than women (53%) favored nuclear. But women were not more opposed; more women (20%) than men (7%) had no opinion. Education also continues to be a factor, as 68% of college graduates, compared with 56% of those

Findings 3 Favorability to nuclear energy, demographic groups (General US Public, April 2019).

Overall, do you strongly favor, somewhat favor, somewhat oppose, or strongly oppose the use of nuclear energy as one of the ways to provide electricity in the United States? (%)

	<i>Favor</i>	<i>Oppose</i>	<i>No opinion</i>
Men	69	24	7
Women	53	27	20
Age: 18–34	57	26	17
Age: 35–49	61	22	16
Age: 50+	64	27	8
College graduates	68	25	7
Not college graduates	56	27	17
Democrat	57	33	11
Republican	73	18	9
Independent	59	26	15
Conservatives	79	15	6
Moderates	58	29	14
Liberals	49	42	9

with less than a bachelor's degree, were in favor in 2019, again due to more college graduates having an opinion. Age differences were minimal, except that more of the public over age 50 had an opinion. Majorities of all political parties favored nuclear energy: 73% of Republicans, 57% of Democrats, and 59% of Independents. Political philosophy shows a wider divide; those favoring nuclear energy included 79% of conservatives, 58% of moderates, and 49% of liberals.

Public majorities have supported specific uses of nuclear energy, including the following propositions, for decades. In 2019, majorities agreed we should:

- Renew the license of nuclear power plants that continue to meet federal safety standards—75% agreed; 16% disagreed.
- Prepare now so that new nuclear power plants can be built if needed in the next decade—67% agreed; 21% disagreed.
- Definitely build more nuclear power plants in the future—55% agreed; 31% disagreed.

Perception gap

The origins of nuclear fear are well described in Spencer Weart's chapter in this encyclopedia, "Public Images of Nuclear Energy." The negative imagery he describes persists today. Because of the negative imagery, it is often assumed that the public opposes nuclear energy, when this is clearly not the case. Over many years, the Bisconti Research survey program asked:

(1) respondents' own opinion of nuclear energy and (2) their perceptions of the opinions of others. Over the years, the data have shown a very large perception gap—that is, the US public perceives public opinion toward nuclear energy as less favorable than their own opinion.

This perception gap can lead persons who favor nuclear energy to fear speaking out in support of nuclear energy. That silence, in turn, could reinforce erroneous perceptions of public opinion. In her book, *The Spiral of Silence*, political scientist [Noelle-Neumann \(1984\)](#) proposed the theory that people fall silent when they perceive that their position on a topic is in the minority, and this silence adds to the perception that the position is unpopular. More silence accentuates the perception and further reduces vocal support in a spiral until the silent side loses.

The 2019 survey found a remarkable change in the perception gap. In 2019, 61% personally favored nuclear energy, and 53% thought that others shared this view. The 2019 finding is especially remarkable because, in three decades of asking the question in slightly different ways, this was the first survey in which a majority of the public (53%) described public opinion as favorable.

This change indicates the possibility of greater attention in the public discourse to nuclear energy as a solution to future energy problems. Are more supporters speaking out? Observation indicates they are doing so ([Findings 4](#)).

Another remarkable finding is that slim majorities across demographic groups described public opinion as favorable. Notably, 58% of the young generation of adults (Millennials and Gen Xers) perceived public opinion toward nuclear energy to be favorable ([Findings 5](#)).

Mushiness

In the 1980s, [Yankelovich \(1991\)](#), in conjunction with *Time Magazine*, developed an index to distinguish issues about which public views were "firm and stable" from those that were "unstable and mushy." Factors associated with greater mushiness include low congruence between one's own perceptions and those of others, low personal engagement, and a low sense of feeling knowledgeable about the topic.

(Includes only respondents who said others favor or oppose)

1983 Question: To the best of your knowledge, are most people in your community in favor of or opposed to nuclear energy? (%)

2016/2019 Question: Do you think that the majority of people in your community favor or oppose the use of nuclear energy? (%)

Findings 4 For the first time in 36 years, more say the majority favors nuclear energy (General US Public). Bisconti Research, Inc. (2019) *Public Opinion on Nuclear Energy: Turning a Corner?* American Nuclear Society.

Findings 5 Perceived favorability to nuclear energy, demographic groups (General US Public, April 2019).

	Do you think that the majority of people in your community favor or oppose the use of nuclear energy? (%)	
	Favor	Oppose
Men	54	46
Women	53	47
Age: 18–34	58	42
Age: 35–49	50	50
Age: 50+	52	48
College graduates	55	46
Not college graduates	52	48
Democrat	50	50
Republican	60	40
Independent	53	47
Conservatives	65	35
Moderates	52	48
Liberals	40	60

Public opinion toward nuclear energy tends to be mushy, Bisconti Research surveys find. It is easily influenced by new information and even by slight changes in the context in which public opinion questions are asked. For this reason, the ability to track the same identical question in the same context is valuable (Bisconti, 2016). A context of discussing environmental hazards and alternative solutions can trigger negative thoughts and images about nuclear energy such as Weart (2021) described in his chapter on “Public Images of Nuclear Energy.” Recently, Gallup has asked the exact same question that the Bisconti Research polls have tracked for 36 years but in the context of questions about environmental hazards. The answers are always less favorable to nuclear energy in that context; in 2019, Gallup found the public divided 49% in favor to 49% opposed; Bisconti Research found 61% in favor to 26% opposed; 13% had no opinion.

What remains in common, even with the influence of a negative context, is that the majority of the public in both surveys sits in the middle—*somewhat* favor or *somewhat* oppose or don’t know. That is another sign of mushiness.

There is a common misperception that a large portion of the public is firmly opposed to nuclear energy because opponents have been outspoken. Those saying they were strongly opposed in 2019 included 21% of those surveyed in the Gallup question context and 8% in the Bisconti question context. Obviously, being strongly opposed does not equal being firmly opposed, as opinions of many potentially strongly opposed respondents change depending on the question context.

Familiarity builds favorability

Surveys consistently have found that few members of the US public feel very well informed about nuclear energy. In 2019, only 19% said they felt very well informed about the topic. These include more men, college graduates, and Millennials and Gen Xers (**Findings 6**).

There is a close correlation between the level of feeling informed on nuclear energy and attitudes toward this energy source. Among those who felt very well informed about nuclear energy, 68% *strongly* favored nuclear, and 7% were *strongly* opposed. Those who felt less well informed tended to express opinions in the middle or no opinion at all (**Findings 7**).

Plant neighbors more favorable

Familiarity is shown to make a difference in surveys of nuclear power plant neighbors. Persons who live near nuclear power plants are overwhelmingly favorable to nuclear energy. Their opinions are the opposite of NIMBY (Not In My Backyard).

Bisconti Research conducted seven biennial surveys of nuclear power plant neighbors from 2005 through 2017. Each survey included at least 1,000 persons selected within the 10-mile radius of the US sites with operating nuclear power plants—59 sites in 2017. The surveys excluded households with people who work at a nuclear power plant and might have a vested interest.

Over the seven surveys, public support has continued to be broad and deep. In 2017, 81% favored the use of nuclear energy, and half were strongly favorable. Those opinions were more favorable than those of the general public who were surveyed at the same time (**Findings 8**).

How well informed do you feel about nuclear energy used to produce electricity? (%)

Findings 6 Level of feeling informed about nuclear energy (General US Public, April 2019).

Overall, do you strongly favor, somewhat favor, somewhat oppose, or strongly oppose the use of nuclear energy as one of the ways to provide electricity in the United States? (%)

How well informed do you feel about nuclear energy used to produce electricity?

Findings 7 Informed about nuclear energy, by favorability to nuclear energy (General US Public, April 2019). Bisconti Research, Inc. (2019) *Public Opinion on Nuclear Energy: Turning a Corner?* American Nuclear Society.

Overall, do you *strongly favor*, *somewhat favor*, *somewhat oppose*, or *strongly oppose* the use of nuclear energy as one of the ways to provide electricity in the United States? (%)

Findings 8 Favorability to nuclear energy (Plant Neighbors and the General US Public, October 2017).

Thinking of the nuclear power plant closest to where you live, would you describe your general impression of this plant and the way it has operated recently as very favorable, somewhat favorable, somewhat unfavorable, or very unfavorable? (%)

Findings 9 Impression of nearby nuclear power plant (Plant Neighbors Surveys).

Those favorable attitudes are grounded in excellent performance, according to plant neighbors. Almost everyone (86% in 2017) reported a favorable impression of the nearby plant and how it had operated recently; 56% were very favorable (**Findings 9**).

When asked about the community's impression of the nearby plant, there is virtually no perception gap appearing in any of the seven surveys. Residents continued to be aware that most people in the community have a favorable impression of the plant: most recently, in 2017, 75% thought most people in their community have a favorable impression, 12% thought they were unfavorable, and 13% were unsure.

Plant neighbors feel better informed about nuclear energy than does the general public; in 2017, 45% said they felt very informed. Of those who said they felt very well informed, 78% were very favorable to the nearby plant, and 1% were very unfavorable (**Findings 10**). Because activism is usually dependent on feeling very well informed without a topic, the chances of nuclear plant neighbors becoming activists in favor of a nearby plant versus opposed to a plant are on average 78 to 1.

Local support is so strong that, in 2017, 68% said they would find it acceptable to add a new reactor at the nearby plant. Just 27% would find it not acceptable, and 5% were unsure. Acceptability slightly declined after Fukushima—from 76% in 2009 to 67% in 2011 and then plateaued at 68% in 2013, 2015, and 2017. This figure is for all US nuclear power plants and is lower in some areas and higher in others. It is clear, however, that there are numerous sites where a new reactor would be readily acceptable. In a time of BANANA (Build Absolutely Nothing Anywhere Near Anyone), nuclear energy has the advantage of extraordinary local support (**Findings 11**).

A 2019 survey of Canadians by Abacus Data also found a similar pattern of greater support for nuclear energy in provinces that are most familiar with the technology. After being told that "nuclear energy produces very little carbon emissions, similar to solar, wind, and hydroelectricity," respondents were asked their opinion on "using nuclear energy technologies in situations where they could replace the use of higher emitting fuels." Nationally, 49% said they would support using nuclear energy in those situations, 35% would be open to it, and 17% would oppose. In Ontario, where much of Canada's nuclear energy capacity is located, most would support (56%) or be open to (34%) substituting nuclear for higher emitting sources; only 10% would oppose. In Quebec province, which does not produce any nuclear energy, 30% would oppose.

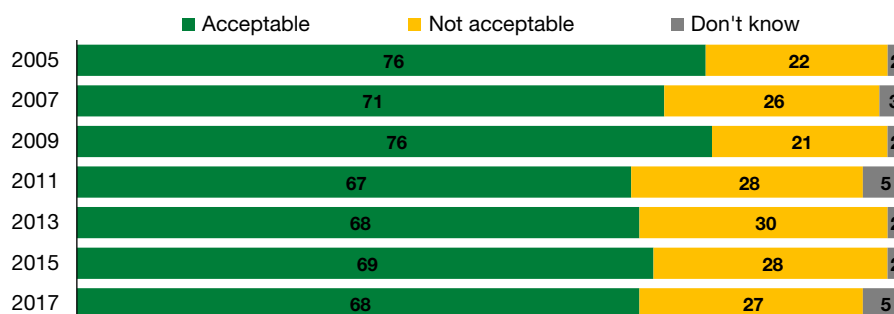

Thinking of the nuclear power plant closest to where you live, would you describe your general impression of this plant and the way it has operated recently as very favorable, somewhat favorable, somewhat unfavorable, or very unfavorable? (%)

Do you feel very informed, somewhat well informed, not too well informed, or not well informed at all about nuclear energy used to produce electricity? (%)

Findings 10 Impression of nearby plant, by how informed residents feel about nuclear energy (Plant Neighbors Survey, October 2017).

If a new power plant were needed to supply electricity, would it be acceptable to you or not acceptable to you to add a new nuclear reactor at the site of the nearest nuclear power plant? (%)

Findings 11 New reactor acceptability (Plant Neighbors Surveys).

Foundations of local public support for nuclear power plants

Local support for the plants is grounded in familiarity, perceptions of safe plant operations, and favorable views of the company regarding safety, the economy, jobs, the environment, and community outreach. Nuclear power plant personnel are actively engaged in community outreach and projects such as support for schools and the local environment (**Findings 12**).

Local voluntary environmental programs around US nuclear power plants are especially extensive and were initiated long before such programs became fashionable among corporations. Because nuclear power plants are often located next to lakes, rivers, or ocean water, they are surrounded by diverse species of wildlife and plants. Several nuclear utilities sponsor parkland near their plants for use by the local community. These programs are on top of clean and safe performance and environmentally safe waste management, both of which are regulated.

A 1995 survey by [Landsberger and Creatchman \(1995\)](#) produced an inventory of US nuclear utility voluntary environmental programs to protect the land, water, and wildlife around their plants. The programs, published in the report, *Nuclear Power Plants and the Environment: 254 Things you Never Knew*, include many activities co-sponsored by environmental organizations such as the Nature Conservancy, Audubon Society, and Boy and Girl Scouts—as well as local government agencies, universities, and community groups. The report cites a manager at an electric utility that owns a nuclear power plant, as follows: “We’re not a manufacturing plant that can just up and move. This is our service territory. We’ve been here, serving this region, for nearly 100 years—and we’re not going anywhere. That gives us a major stake in preserving the beauty of the area.”

In addition to programs such as those to protect the environment, the nuclear utilities put considerable effort into energy education and outreach. Energy education centers were once the focal point for their energy education. These centers, like mini-museums, included exhibits and personnel to explain energy, nuclear energy, radiation, waste management, and other topics of interest. These centers were open to passersby from anywhere, as well as to the local community. They also served as places for community groups to hold meetings. After the 9/11 attacks and the increased imposition of security everywhere,

Findings 12 Percent agree with statements about company that operates the nearby nuclear plant (Plant Neighbors Survey).

Now, I'd like to ask you about the company that operates the nuclear power plant nearest to you. Please tell me if you strongly agree, somewhat agree, somewhat disagree, or strongly disagree with the following statements about this company. (%)

	2005	2007	2009	2011	2013	2015	2017
I am confident in this company's ability to operate a nuclear power plant safely.	88	87	91	87	89	90	88
I am confident that the company has prepared the plant to withstand the most severe natural events that may occur in this region.	n/a	n/a	n/a	79	83	82	81
This company is doing a good job of protecting the environment.	84	81	86	84	82	83	79
The plant helps the local economy.	n/a	n/a	90	87	91	89	90
There are good jobs for local people at the plant and in local businesses that provide services to the plant.	n/a	n/a	89	87	87	89	87
This company is involved in the community. (<i>"...as a good citizen."</i> 2005)	83	77	83	76	80	81	78

centers located within the boundaries of the plants had to be closed. Plant tours, another important education vehicle, also were largely curtailed.

Personnel from nuclear power plants still actively engage with local community groups and schools. In some cases, the companies organize outreach formally. A model is the Fan Team approach used by the nuclear utility Baltimore Gas & Electric for two-way communication with the community before seeking license renewal of the Calvert Cliffs plant—the first plant to seek license renewal in the United States. Designated personnel, like spokes on a fan, took information to their peer groups and brought back questions and opinions from these groups to a central point. The result was that the community gained a good understanding of license renewal, and the company had a good understanding of public opinion.

The local newspaper reported the results:

We are sure some of the opponents to relicensing Calvert Cliffs Nuclear Power Plant were left confused following a hearing last week. Critics of the utility and the Nuclear Regulatory Commission denounced the relicensing process as well as nuclear energy. Then what happened next was a little startling. Calvert Cliffs residents stood up and told them to leave their plant alone. That Baltimore Gas & Electric had been a good neighbor. (*The Calvert Recorder*, 1999)

Some nuclear power plants report that establishing Community Advisory Groups has been helpful in engaging the public and creating more ways for two-way communication. They have been used, for instance, for advising the utility on community interests when storage facilities for spent nuclear fuel are built on the plant site or when a plant is being decommissioned.

Building support beyond local communities

Expanding familiarity to a population of millions is obviously challenging. Beyond local communities, the general public can best be reached when there is something related to nuclear energy that is on their minds. For example, when the Chernobyl accident occurred in 1986, there was vast interest in the safety of nuclear power plants. Quick research showed that the public was greatly reassured to learn about the main differences between the Chernobyl plant and those in the United States. The industry launched an advertising campaign that explained, "Why What Happened at Chernobyl Did Not Happen at Three Mile Island." The advertising showed the containment structure that surrounds US reactors and did not surround the Chernobyl plant. It also, for the first time, communicated the reality of the Three Mile Island accident—that no one was harmed. It helped that the news media, politicians, and even some nuclear critics reiterated these same themes.

The result was remarkable. Although Chernobyl caused a slight drop in favorability to nuclear energy, the ratings of the safety of nuclear power plants became slightly *more* favorable than before. The ratings of nuclear power plant safety then began an upward trend that continued with a couple of aberrations until a descent following the Fukushima accident in 2013 (**Findings 13**).

Today, nuclear power plant safety is not part of the public discourse. The tremendous influence of the Institute of Nuclear Power Operations on safety, including changes to all US plant operations based on lessons learned from Three Mile Island and Fukushima, is reassuring but is not a current topic for the news media. The ongoing daily oversight of all US plants by the Nuclear Regulatory Commission (NRC) and the fact that, if a nuclear power plant were not operating safely, the regulator would shut it down, is also very reassuring but not a current news topic.

Thinking about the nuclear power plants that are operating now, how safe do you regard these plants? Please select one number on a scale of “1” to “7” where “1” means very unsafe and “7” means very safe. The safer you think they are, the higher the number you would give.

Findings 13 Perceptions of nuclear plant safety more favorable over long term (General US Public).

Today, the energy related topic that is on the public mind and of interest to the news media is environmental, including clean air, carbon-free energy solutions, and transitioning away from fossil fuels. Within that context, there is a great deal of innovation taking place at the national laboratories and in private industries that can convey to the public that the nuclear energy enterprise is thriving. A thriving industry seems safer than one that is on its last legs. Some of that innovation is exciting and includes different sizes of reactors to meet different location needs. Innovative nuclear reactor designs can make real the promise that nuclear waste does not have to be wasted: some of them use the waste to create electricity and others can minimize waste.

These innovations are consistent with the international Clean Energy Ministerial that is taking a fresh visionary look at energy systems of the future in which nuclear energy can supply electricity, as well as clean drinking water, heat, hydrogen, and support for variable renewables.

The industry should not fear that talking about the technological advancements might shed a bad light on the current fleet, as the public expects a thriving industry to evolve and improve its products. Negative impact will happen only if those promoting new reactors disparage the current fleet by calling existing reactors unsafe, outdated, or old. None of those claims is true, as is evidenced by the fact that if a plant were unsafe the Nuclear Regulatory Commission would shut it down. All the existing plants are continually updated with new technology.

The interest in technological discussions extends to preferred spokespersons. Americans would prefer, by a wide margin, information from nuclear scientists and engineers, as well as from a safety engineer at a nuclear power plant in their area. Research finds consistently that plant neighbors and the general public both give greatest credibility to persons with hands-on experience with the technology (**Findings 14**).

Given the option of using solar or wind, there needs to be a compelling reason to use nuclear energy. Public discussions about climate change solutions often fail to mention nuclear energy even though nuclear energy produces more than half the US carbon-free energy. Even more important, nuclear energy offers *both* clean air and reliable electricity. It is the only carbon-free source of electricity that offers both in large quantities day in and day out. It keeps on generating electricity when the wind doesn't blow and the sun doesn't shine. Those are compelling reasons.

In fact, the public agrees, as seen in answers to questions designed to test messaging *after* completing the trend questions about public opinion. Most recently, in the 2019 survey, 75% agreed with the following statement: "We should take advantage of all carbon-free energy sources including nuclear, hydro, and renewable energy to produce the electricity we need while limiting greenhouse gas emissions" (**Findings 15**).

The survey continued: "Nuclear energy produces more than half of all the carbon-free electricity in the United States. And given that nuclear energy is the only electricity source that provides both clean air and continuous 24-7 electricity, do you think nuclear energy should be very important, somewhat important, not too important, or not important at all in the future?" Given these points, three-fourths said nuclear energy should be important (**Findings 16**).

In the 2019 national survey, respondents were asked to rate the importance of considerations for the way electricity is produced. All of them are attributes of nuclear energy. The considerations given highest importance were reliable electricity, affordable electricity, and clean air. More than 60% rated each of them "top" in importance. Other attributes given top or medium importance by almost everyone were: efficiency, energy security, economic growth, job creation, climate change solution, and resilience.

The concept of resilience, the ability to resist natural disasters, has been on the lips of policymakers recently due to dramatic disasters that many observers link to climate change. Nuclear energy plants can claim resilience, as their plants continue to provide electricity when many other types of plants are forced to shut down. That attribute trailed the others in the importance given, largely because the concept could have many meanings other than the ability to resist natural disasters (**Findings 17**).

In multiple surveys, clean air scores as a top consideration in electricity production, but climate change does not. There is strong agreement across political parties on the importance of clean air but a partisan divide on climate change: fewer Republicans assign

Please tell me if you think each of the following would be an excellent, good, fair, or poor source of accurate and reliable information about nuclear energy. (%)

Findings 14 Percent rating information sources excellent or good.

Please indicate if you strongly agree, somewhat agree, somewhat disagree, or strongly disagree with the following statement. We should take advantage of all carbon-free energy sources including nuclear, hydro, and renewable energy to produce the electricity we need while limiting greenhouse gas emissions. (%)

Findings 15 Agreement with using carbon-free energy mix, including nuclear, hydro, renewables (General US Public, April 2019).

Nuclear energy produces more than half of all the carbon-free electricity in the United States. And given that nuclear energy is the only electricity source that provides both clean air and continuous 24-7 electricity, do you think nuclear energy should be very important, somewhat important, not too important, or not important at all in the future? (%)

Findings 16 Importance of nuclear energy as a carbon-free electricity source (General US Public, April 2019).

Following are some considerations for the way electricity is produced. For each one, indicate if that consideration for the way electricity is produced is of top importance to you, medium importance to you, or low importance to you.

Findings 17 Top considerations for electricity production (General US Public, April 2019).

Greenhouse gases, such as carbon, may cause climate change. For each source of electricity that I'll read, please tell me if you think it releases a lot, a little, or no greenhouse gases, such as carbon, into the air. (%)

Findings 18 Perceived sources of greenhouse gas emissions (General US Public, March 2014).

top importance to climate change. Nevertheless, in 2019, 60% of Republicans assigned at least medium importance to climate change, indicating at least openness to climate change messages.

The challenge in gaining entry into climate change discussions is that few members of the public recognize nuclear energy's large clean air role. In a Bisconti Research survey in 2014, only 25% answered that nuclear energy releases no greenhouse gases, compared with more than 70% for wind and solar energy (**Findings 18**).

In 2019, Abacus Data asked a sample of 2500 Canadians about the carbon impact of six sources of electricity: "Does using these energy sources create more carbon pollution than oil, about the same or less?" Only 38% of the public knew that nuclear energy creates less carbon pollution than oil. That compares with 82% for solar, 80% for wind, and 63% for hydro.

Implications

Despite the majority public support, there is no doubt that a stigma still attaches to nuclear energy and all things associated with radiation. The origins of this stigma are well chronicled by Weart (2021). Education about radiation with attentive audiences such as students and Scout troops is helpful. Some communities encourage their residents to measure radiation by handing out Geiger counters; they are, in fact, empowering the public with hands-on tools. For the broad inattentive public, just hearing information about radiation could trigger the old ingrained phantasmagoric images. Instead, the best way to reduce the stigma is to make the beneficial uses of radiation normal and well known—familiar (Bisconti 2011). In the case of nuclear energy, the more people see it to be needed, the less they see danger. Useful information on nuclear energy's benefits is provided by Hor-Lacy (2021), Waltar (2021), and by Bezdek (2021).

Today, the public senses that nuclear energy is needed, but they do not articulate a focused reason why it is needed. Nuclear energy has an essential role as the one energy source that delivers a large amount of carbon-free energy reliably all day every day. Learning about nuclear energy's unique role for meeting climate change and clean air goals greatly increases support.

A focused message about nuclear energy's contribution needs to be heard widely in order to build support. In the words of World Nuclear Association Director General Rising (2019): "The 445 nuclear reactors in 30 countries are the low-carbon backbone of electricity systems, operating in the background, day in day out, often out of sight and out of mind, capable of generating an immense amount of clean power. They are the silent giants upon which we rely today." Silence is the enemy of winning public hearts and minds.

Time and effort by those who recognize nuclear energy's important clean air value will be necessary. They must focus communications on vision for the future and a world with clean and abundant energy. That may include the innovations that support this future vision. The vision of nuclear energy as a part of the solution to major societal concerns gains substance by telling the interesting story of nuclear energy innovation, including the ongoing work of the national labs.

The fact that the perception gap may be narrowing—the public perception of public opinion was more favorable in 2019—suggests that more positive messages about nuclear energy's contribution are reaching the public. Credit is due to the many nuclear professionals and environmental advocates who are giving valuable time to outreach.

Introduction

Concerning any energy technology important questions are those of the human health and environmental hazards that it might pose and the cost—benefit balancing that could affect the acceptability of these hazards. For civilian nuclear energy experience and all except politically partisan analyses have indicated that the health and environmental risks of the technology are small compared to those of other energy technologies. In its current form the technology provides mainly electricity, a commodity available from many other technologies as well. Consequently, the benefits of using nuclear technology are not valued highly, at least in wealthy countries, and the risks, while small, are also sufficiently uncertain for many people that the balancing does not lead to nuclear acceptance. This balancing is sometimes different in rapidly developing societies where the energy supply diversity offered by nuclear is more appreciated, and its risks are seen as being relatively smaller.

Hazards overview

Table 1 compares the types of environmental and health hazards of many of the currently competing energy technologies. It is organized according to different facility life cycle stages, and reflecting accidental hazards. It is seen that technologies using fossil fuels have more entries in different categories, with coal being the most dangerous fuel, followed by petroleum and then by natural gas. Among the remaining technologies nuclear has fewer entries than those using fossil fuels, but more than some of the renewable energy technologies (e.g., wind and solar PV). Notably hydroelectric is a renewable energy technology that has been responsible for many fatalities killing scores of persons every few decades yet it is not viewed as being more hazardous than nuclear energy. Some technologies have chronic health consequences that show up as actuarial evidence, as with excess mortalities and morbidities from environmental pollution (e.g., coal and petroleum—to a lesser degree). Other technologies evidence accidental hazards, especially any involving underground mining (i.e., coal and uranium-in the past). Corresponding quantitative results from several studies are provided by [Haddad and Dones \(1991\)](#) and excerpted in **Table 2**.

Radioactive materials

Nuclear energy is special as it involves radioactive materials. The doses to workers are greater than to the general public, and for both groups are at levels where there is considerable expert disagreement from whether any effects exist to the position that the actual effects upon which public and occupational protection policies are based are in reality underestimated. The problem here is that the scientific foundation for reaching conclusions in this exposure range is still substantially nonexistent. The arguments that no effects should be expected range from expectations that natural repair of radiation effects will occur-given that the Earth's organisms have evolved in previously more intense radioactive environments than obtain today. The arguments that actual effects are being underestimated are based upon suspicions that all or most radiation effects are harmful. In democracies the actual experience with radiation has been that no radiation related fatalities or serious injuries have been observed in connection with the four reactors

destroyed in the Three Mile Island and Fukushima Daiichi accidents. Also, in those cases the offsite radiation levels typically stayed below occupational exposure limits. However, these events were very scary. Democracies have shown that they are unwilling to tolerate such stressful experiences, regardless of how small their actual consequences turn out to be.

The only other core damage event involving civilian nuclear power was that in 1986 at Chernobyl, Ukraine, where 32 firefighters died due to acute radiation exposures. Many others in surrounding regions may have been exposed to lower doses. The reality will likely never be known as data on both exposures and effects were not well developed following the event. As a consequence, a broad

range of estimates of both have appeared. This event has largely been viewed as the consequence of operational practices and faulty reactor design reflecting causes associated with the societies of the Soviet Union and allied states, and not with nuclear energy operations encountered elsewhere (Sich, 2021). The Chernobyl experience carries a lesson of the need for care in nuclear power operations to ensure that operational practices are well-designed and adhered to. This lesson is probably most important in developing countries, especially those new to using nuclear technology, where the safety practices may not be as demanding and strictly adhered to as in the industrialized democracies. The overall lesson is that nuclear power has radiation hazards that can be managed successfully, but also that can be harmful if not managed carefully.

Most assessments of nuclear energy hazards reflect broad uncertainties, as the theoretical and data base needed for high accuracy have not yet been developed—reflecting a lack of clearly attributable harmful effects of radiation. A good example of this is reflected in Table 2, summarizing prior estimates of electricity related health risks.

Important causes of mortalities include explosions of natural gas pipelines, collisions with freight trains carrying coal, flooding following hydroelectric dam failures and facility construction accidents. Radiation related fatalities due to accidental releases from nuclear facilities have been widely feared but not realized, except in the case of the 1985 Chernobyl reactor explosion, which was more of a Soviet Union cultural failure than a technological accident (Sich, 2021). Public disease mortalities have arisen mainly from fossil fuel-related air pollution. In cases where the theoretical basis is substantially uncertain high values of estimated mortalities are associated with pessimistic assumptions, but without clear evidence, about the extremes of causality, as with radiation, water pollution, electromagnetic field and air pollution effects.

Radiation dose sources and public ignorance

Radiation exposures to the general public are dominated by those for medical (i.e., cancer) therapy and imaging, with natural sources of radiation (cosmic radiation and those from naturally occurring radioactive decay of elements that are part of the Earth crust), miscellaneous sources such as cosmic radiation encountered in high altitude flying. Cancer treatment doses are of the order of 1000 Rad or 10 Gy; naturally occurring and occupational doses are typically four orders of magnitude smaller. That is, industrial exposures, including those due to nuclear energy, are negligible (Nichols and Byrne, 2021). Despite this reality radiation associated with nuclear energy is and has long been viewed by many people as a serious hazard. This belief has been persistent over several decades, and appears to be fundamental to popular attitudes concerning the acceptability of the nuclear technology.

The combination of hypotheses has been offered to explain this persistence. The main elements identified include both scientific and popular ignorance, a literature reflecting scary themes dating back roughly a century (Weart, 2012, 2021), introduction of powerful nuclear technologies via use of nuclear weapons in 1945—followed about a decade later by the United States' leadership in establishing the UN's Atoms for Peace program to develop civilian nuclear energy internationally—all in the context of the cold war and nuclear competition with the Soviet Union until 1991.

The universe has been created and powered by nuclear reactions from the beginning of time (Previtali, 2021). Without them there would be no universe. Life on earth has evolved in a persistent and decreasingly intense environment of ionizing radiation. The biological effects of such radiation at high doses and rates has long been recognized as potentially harmful. The corresponding state of knowledge for low-dose and low-dose rate exposures still remains to be developed. Extrapolation from high dose experiences to low-dose ones has been made in order to permit occupational and public exposure standards to be formulated. However, it remains recognized that the basis for such extrapolation has not been well established. Rather, the linear, no threshold model of radiation dose-health effects has been adopted as a social expedient. The corresponding uncertainty has allowed various social interpretations concerning radiation and the risks of exposures to take hold. Some of these have led to strong opposition to use of alternative models ranging from ones of beneficial effects to those of more severe adverse effects. These disagreements are likely to persist, perhaps far into the future, until the state of biophysical understanding becomes much more advanced (for more on this see Nichols and Byrne, 2021).

Nuclear fission and societies

Despite their foundational roles in creating our reality nuclear reactions entered human consciousness only very recently, via discovery of radioactivity by Antoine Henri Becquerel at the end of the 19th century. Thus, it is not surprising that many people view nuclear phenomena as a recent alien intrusion; and a mysterious, dangerous threat.

Nuclear reactions were of little practical importance until the 1930s when the fission reaction was discovered by O. Hahn and F. Strassmann in collaboration with L. Meiter and O. Frisch. It is an essential phenomenon in both nuclear weapons and in civilian nuclear power. It occurs by exciting a heavy nucleus via neutron absorption. The excited nucleus splits typically into two fission fragments, and associated nuclear particles. In doing this it releases approximately a 100 million times the amount of energy obtained from a single chemical reaction. Thus, a small mass of nuclear fuel can store a large amount of potential energy, that when released can be very destructive (as with nuclear weapons) or can be a long duration energy source (as with nuclear powered ships). The fission reaction products also constitute nuclear wastes and create the radiation environment of nuclear energy which renders nuclear systems more difficult to manage, and their failures more difficult to recover from.

Initially support for both civilian and military nuclear applications was strong, reflecting their contributions to success of the allies in World War II and then in competition with the Soviet Union. This included the Atoms for Peace program, especially within the United States, where it originated, and where support was quite strong. A broad consensus existed that nuclear technologies, especially for naval propulsion, energy and medicine, were beneficial and that their use should be promoted internationally. Subsequent literature, (Slovic and Peters, 2006) has developed seeking to explain later popular rejection of technologies, including nuclear, seen to be hazardous. Causal factors cited include individual unfamiliarity with the technologies, remoteness of the facilities and their operators from ordinary experience, unknowability of the harmful agents (e.g., invisible, odorless, mysterious, as with radiation) among others. The validity of this literature is challenged by the previously broad acceptance of nuclear technologies. It is credible that other factors, such as a loss of trust in authority figures maybe more important.

Nuclear power in the United States

Such support persisted until 1963 when the US became involved in the Vietnam War, which lasted until 1975. That involvement coincided with the advent of the US civil rights movement, the environmental protection movement and growing opposition to civilian nuclear power—particularly by challenging its technological soundness, especially concerning safety. From the 1960s onward, a persistent criticism was that nuclear power was too dangerous to be used, and that the American policy elite had deceived society via its promotion. This charge can be understood as a means of opposing the war, where the means of opposition were opposition to the war itself, and challenging the legitimacy of national policies generally. As the civilian nuclear power program was a flagship US national enterprise attacking the program was an attractive way to oppose the war policy.

This view was reinforced later by the 1979 Three Mile Island accident, which caused no radiation related injuries, but was attributed to have been an important cause of mental health problems. More importantly, that event cause a loss of confidence in the leadership of the worldwide nuclear power enterprise. These changes overthrew the previously uncritical pro-nuclear consensus. Implicitly support for all of the popular movements mentioned here reflected broad dissatisfaction with national policies and constituted demands for change.

These factors have been influential to the point that a little less than half of the approximately 180 nuclear power reactors ordered in the United States ultimately did not go into operation, and only two reactors ordered since 1974 appear today to be approaching operation. Other factors contributing to this result have included the disappointing financial and regulatory experiences of many of the units initially ordered during the 1970s.

It is important to note that anxieties about radiation risks have not been substantiated, but still have powered an effective prohibition since the 1970s on the growth of the civilian nuclear power enterprise. This comes about not through a formal policy, but rather from creation of a highly unstable project management environment that renders the probability of successful completion of a new power reactor facility low enough to deter investors. The safety regulatory system is especially important in this, as it has ended up being unpredictable, slow and expensive to deal with. In the rest of the world growth of the nuclear power economies has been steadier, partially reflecting the more typical situations that nuclear safety regulation excludes citizen participation in licensing of individual units—a major source of construction project instability that is unique to the United States.

This system has also hindered innovation, such that the dominant nuclear power technology of today uses light water-cooled reactors, derived from submarine propulsion systems, that was introduced at the start of the Atoms for Peace Program for achieving a quick, inexpensive, politically-inspired success. It then became ensconced worldwide via the technology lock-in process. This technology is good enough for utility level electricity production, but not for important innovative roles such as aiding decarbonization of the global energy economy. Other reactor concepts, capable of much higher temperatures and large power capacity, consistent with safety and environmental compatibility, such as those cooled by gas, molten salts or liquid metals appear much better suited for such role (for more on this see Stanculescu, 2021). Some of these have been taken through the early stages of development and commercial introduction, but have not yet achieved large scale marketplace success.

The nuclear power enterprise has been engaged for more than six decades, resulting in the approximately 450 nuclear power reactors operating worldwide. In three countries it is the most important electricity source, and most industrialized countries have a nuclear power industry. It has an excellent occupational safety record, being one of the safest industries for workers in the world (although the quality of the results observed reflect differences in the different societies, all using essentially the same technology).

Weighing of risks and benefits

In the face of this positive record the question arises as to why nuclear power has not been embraced popularly since the end of the Vietnam War in 1975, at which time the anti-war genesis of nuclear opposition became moot. A plausible explanation is that this technology is viewed as being possibly hazardous and safe enough when managed well, but without strong redeeming benefits. For many people this combination can provide sufficient justification for being wary and reluctant to invest in efforts to understand matters more deeply. Civilian nuclear energy is simply one means of obtaining electricity, which is available at low costs from many sources. Consequently, this weak benefit-cost comparison can be a sufficient explanation for lack of enthusiasm for using this technology. The contrasting example of commercial flying, where hazards are evident on an actuarial basis yet the demand

for flying remain strong illustrates the effect of cost-benefit balancing upon popular technological acceptance. In the case of flying the convenience that it provides is valued sufficiently that people are willing to expose themselves to potential, and clearly evident, destruction in order to capture it. Should nuclear energy come to be seen as providing substantially higher benefits—as in saving the planet from global warming—conceivably popular preferences could change strongly and quickly.

Nuclear energy and climate change

Should nuclear energy come to be used more broadly throughout the world these culturally dependent outcomes may prove to be more important than those arising from technological factors. This dependence of nuclear success upon human decisions and practices is a little recognized, but very important aspect of factors affecting civilian nuclear power performance, and may be central to the future acceptability of the nuclear enterprise.

A particularly important reason for a much larger future role for nuclear energy is its ability to contribute to mitigating climate change. It is currently not exploited near to its potential in reducing use of fossil fuels, an essential condition for ending global warming. In the technological portfolio for such a response a combination of the renewable energy technologies, nuclear and efficiency improvements combined with an energy storage capability has become recognized as being economically more attractive than a sparser toolkit. This outcome results from the greater benefits of the complementary strengths of the diverse elements of the portfolio, and less need to utilize any particular technological options in its domain of decreasing benefits. For example, the intermittency of many of the renewable energy technologies causes the effective marginal costs of an expanded role to increase as its role grows. This is due to need for greater investments in back up energy sources such as batteries, and in the grid capable of dealing with a broader range of operations. This outcome can be avoided when the renewables are used in combination with steady generation sources such as nuclear energy. Recent studies (Sepulveda et al., 2018) indicate that costs of mitigation decrease and decarbonization success probabilities increase substantially by using a more diverse portfolio.

Currently persistent suspicion of the hazards of nuclear energy have discouraged its inclusion in the portfolio. This may be a dangerous choice for humanity, as current nuclear technologies can be useful, but are not designed for climate change mitigation. It takes time and investments to create better technological choices. If the decision to pursue them is delayed too long the needed results cannot be obtained in time for an effective implementation of new facilities. Thus, the stakes are high and decisions based upon perceived risks may deserve reexamination.

Glossary

Baseload generation A generation plant that operates at roughly full capacity throughout the day and week.

Capacity expansion and dispatch model A mathematical program that optimizes the capacities across a portfolio of alternative generating technologies, and the dispatch of those capacities to generate electricity. A typical optimization criterion is lowest total cost, including investment cost and operating cost. A primary constraint is that electricity generation in each period exactly equal load in the period. Another constraint is that aggregate emissions remain below some cap.

Capacity factor The actual generation of a power plant or set of power plants over a window of time divided by the potential generation.

Carbon intensity Carbon emissions per unit of output. For the electricity sector one commonly used measure is grams CO₂ per kilowatt hour of generation (g CO₂/kWh).

Cross-cutting technologies Technologies that are relevant across different reactor concepts. For example, ultra-high performance concrete can be utilized for light-water reactors as well as for molten salt reactors.

Deep decarbonization A reduction in carbon emissions of between 80% and 100% from 1990 levels.

Firm, low-carbon resources Generation technologies that can reliably operate as needed, especially in hours when renewable resources such as wind or solar are unavailable.

Fuel-cycle services Manufacture and handling of nuclear fuel. Handling of used fuel and waste, including storage, processing and waste disposal.

Generation-III reactors It is common to classify reactor designs according to "generation." Generations I includes the early designs deployed by industry in roughly the 1950s and 1960s. Generation II designs begin in the late 1960s and include a large fraction of plants in operation today. Generation III are the most modern designs which began deployment in the 1990s. The overwhelming majority of Gen III reactors are Light-water reactors (LWRs).

Generation-IV reactors The next generation of reactor concepts, only now coming into actual construction and operation. The term is also often used to distinguish new, alternative reactor concepts from the light-water reactor (LWR) concept since most Gen IV concepts are not LWRs. For example, Gen IV concepts include high-temperature gas-cooled reactors, molten-salt reactors and liquid metal cooled fast reactors (Stanculescu, 2021).

Levelized cost of electricity (LCOE) The average cost of electricity generated by a given technology, including the investment cost of the installed capacity and the operating cost. The LCOE varies with utilization as measured by the capacity factor. A higher capacity factor lowers the LCOE since the fixed investment cost is amortized across a larger number of units of generation (Rothwell, 2021).

Light-water-reactor (LWR) This is the overwhelming majority of reactors in use today for generating electricity. Water serves as both the coolant and the neutron moderator. Light-water is the common form of water and stands in contrast to heavy water.

Load curve A representation of the temporal variation of aggregate load throughout the year. Usually reported at hourly granularity, and in the form of a duration curve with the hours ordered not in temporal sequence but by the size of the load.

Load-following generation A generation plant that cycles its output level with fluctuations in load, usually through the diurnal and weekly pattern.

LWR See light-water-reactor.

Peaker generation A generation plant that is utilized infrequently, to meet the peak hours of load.

Premature closure Generally refers to closure prior to the expiration of a plant's license or life as a result of economic pressures.

Production credits A monetary subsidy per unit of electricity sold. This is paid on top of the wholesale market price received from sales. Similar to production tax credits, except that it is a direct payment independent of the company's tax status.

Prototype reactor An early version of a reactor design, usually small scale and built to experiment with and demonstrate operation of the reactor. In general usage, there is significant overlap with the terms demonstration reactor and first-of-a-kind

reactor. In US Nuclear Regulatory Commission regulations the term prototype reactor has specific meaning with respect to licensing requirements.

Reactor concepts Reactor designs that differ in fundamental ways. For example, a light-water-reactor design is a distinct reactor concept from a gas-cooled reactor.

Renewable resource The determinant of output for renewable generation technologies, such as the specific power of the wind (watts per meter squared, W/m^2) or the level of solar irradiance (watts per meter squared, W/m^2).

Small modular reactors (SMRs) A new variant of light-water reactor (LWR) which is much smaller than the traditional LWR design. Multiple reactors, or modules, can be deployed within a single power plant to create flexibility in scaling the plant. Other reactor concepts beside LWRs can also be designed as SMRs (Ingersoll, 2021).

System cost The aggregate cost of serving load. Different technologies may serve different portions of the load curve, and the cost of serving these different portions vary. The system cost is the cost of all the technologies used to meet the full load curve. System cost is contrasted with LCOE since the LCOE is typically reported for a single technology serving a portion of the load curve.

Introduction

The 21st century confronts the world with the twin challenges of expanding energy access to billions of people while simultaneously slashing greenhouse gas (GHG) emissions. Electricity has been the world's fastest-growing form of energy for many decades and it will likely continue to be so for decades to come. In the US Energy Information Administration's (EIA) Reference Case scenario net electricity generation worldwide is growing by almost 84% to mid-century, from 24.1 trillion kilowatt hours (kWh) in 2017 to 44.2 trillion kWh in 2050 (U.S. Energy Information Administration, 2019). Non-OECD countries record the strongest growth at 2.3% per year, while in the OECD countries the average projected growth rate is 1% per year.

This expanded access to electricity will benefit the global population enormously, but the large GHG emissions it could entail represent a clear and present danger to humankind. Already, "[h]uman activities are estimated to have caused approximately 1.0 °C of global warming above pre-industrial levels..." according to the Intergovernmental Panel on Climate Change (IPCC, 2018). In order to limit the global temperature increase to around 1.5 °C or 2.0 °C, total CO₂ emissions need to be reduced to net zero by around 2050 or 2070, and be further reduced to net negative thereafter. In contrast, the EIA's Reference Case shows CO₂ emissions growing by almost 23% to mid-century.

Deep decarbonization of the electricity sector is key to simultaneously meeting the need for energy access while drastically reducing emissions. This is both because the costs of significant emission reductions in this sector are believed to be lower than in other major energy sectors, and because electrification is seen as a tool for decarbonizing other sectors such as transportation and building conditioning. Table 1 benchmarks the task. It contrasts the recent historical level of carbon intensity of the electricity sector with the 2050 goal established for a scenario developed by the International Energy Agency (2017) to be consistent with a 2 °C target for global warming. For example, the 2014 level in the United States was 486 gCO₂/kWh, while the 2050 goal is 11. For China in 2014 it was 698 g CO₂/kWh, while the 2050 goal is 24. Much more stringent goals are also widely advocated by various organizations and experts.

Nuclear power is a dispatchable, low-carbon technology. It is the largest source of low-carbon energy in the United States and Europe, and the second largest source worldwide after hydropower. However, the growth in low-carbon generation in recent years has been dominated by wind and solar technologies. Most outlooks for the future out to 2050 see this dominance continuing due to the falling cost of these technologies. While the increasingly urgent need for more low carbon electricity is an opportunity for the nuclear industry, the prospects for the expansion of the industry remain measured overall, and decidedly dim in many parts of the world. For example, the EIA's Reference case reports an average annual growth rate for nuclear of approximately 1% over the years 2018–50, while the average rates of growth reported for wind and solar technologies over this long period are 4.9% and 7.2%, respectively.

Table 1 Carbon intensity of the electricity sector (g CO₂/kWh), 2014 actual versus 2050 scenario goal.

	2014	2050
World	540	35
United States	486	11
China	698	24
Europe	350	11

The outlook for nuclear varies greatly by country and region. Anticipated growth is concentrated in non-OECD countries. The EIA's Reference Case reports an average annual growth rate for both China and India above 4% over the years 2018–50. Smaller non-OECD countries also have noteworthy plans to develop new nuclear capacity. For example, in the United Arab Emirates, four Korean-designed nuclear power reactors with combined capacity of 5.6 GWe are being installed at the Barakah site, with the first unit complete and scheduled to go on-line in 2020. In contrast, overall nuclear capacity is expected to decline in the United States and in the OECD portion of Europe. In Japan, capacity is expected to remain below one-half of the pre-Fukushima level through 2050.

Many factors are at play in these outlooks, but one fundamental problem is cost. As other low-carbon generation technologies have become cheaper in recent decades, new nuclear plants have only become costlier (Rothwell, 2021). This disturbing trend undermines nuclear energy's potential contribution and increases the cost of achieving deep decarbonization. A recent MIT study on *The Future of Nuclear Energy in a Carbon-Constrained World*, analyzed the opportunity as well as the steps needed to arrest and reverse that trend (Buongiorno et al., 2018). This paper summarizes some of those results.

The opportunity for nuclear energy in a decarbonized electricity system

Looking out to 2050, we asked the question, what are least-cost mixes of generation technologies to serve loads in diverse regions while achieving targeted reductions in carbon intensity, and where does nuclear power fit into those mixes? We paid particular attention to how the accelerated growth of variable renewable technologies, such as wind and solar Photo-Voltaic (PV), alter the optimal portfolio mixes and nuclear's place in these new mixes. To address the question, we applied a capacity expansion and dispatch model to the conditions in a variety of regions with different load and renewable resource patterns. We chose six regions in total, two in the United States—New England and Texas—two in China—the Tianjin, Beijing and Tangshan region and the Zhejiang region—and two in Europe—France and the United Kingdom.

We used the GenX model, which is a constrained optimization model that determines the least-cost mix of investments required to serve electricity demand in a future planning year (Jenkins and Sepulveda, 2017). The optimization criterion is total system cost, which includes the capital expenditures required to install the capacity, as well as the operating expenditures incurred running the capacities installed. The model assumes that once capacity has been installed, it is dispatched and operated to minimize the total system cost, subject to constraints. The constraints include the requirement that net generation equal load in each of the 8760 h of a representative year, taking into account the availability of storage and demand response. Hourly renewable generation is constrained by installed capacity and by the hourly availability of the renewable resource.

Generation units must operate within their technical constraints, such as minimum load, maximum ramping capacity and so on. For example, we assume that nuclear plants have a minimum generation level of 50% and can ramp at a rate of 25% per hour, while gas turbines have a minimum generation level of 24% and can ramp 100% per hour. Finally, aggregate CO₂ emissions must be within a specified constraint. GenX can be configured for different levels of detail. For example, it can incorporate opportunities for demand response, in which customers can displace consumption away from peak load hours, although the study discussed here did not include them. It has the capacity to incorporate certain defined transmission constraints, although the study discussed here treated each region as if there were no transmission constraints within the region and no trade outside the region. Trade across larger regions can serve as a partial substitute for firm, dispatchable generation, but we believe our chosen regions are large enough to extract useful lessons. The model can be parameterized to include existing capacity and to choose new investments, although the study discussed here focused on a greenfield mix for 2050—i.e., with no inherited capacity. The exception is hydro facilities which were fixed at the existing level.

The model requires inputs on the set of available technologies, their operating constraints, and the capital and operating costs. For example, the technologies included in the study discussed here were: utility scale solar PV, on-shore wind, LWR nuclear, natural gas with carbon capture and sequestration (CCS), coal with CCS, open cycle gas turbine (OCGT), combined-cycle gas turbine (CCGT), coal (IGCC), pumped-hydro storage, and battery storage.

This is obviously a limited set of technology options. However, the range of options is broad in terms of key characteristics. Moreover, technologies compete among each other in important ways. Adding additional technologies would provide granularity to the results, but would not affect the key conclusions.

A portfolio optimization that looks at total system cost is essential, and far superior to casual comparisons of levelized cost of electricity (LCOE) numbers for competing technologies. LCOE comparisons assume that technologies are competing head-to-head to serve similar loads. In reality, technologies are often best suited to serve certain portions of the load, and ill-suited to serve others, so that what may seem to be competing technologies are actually complementary technologies on a system.

Historically, because dispatchable thermal technologies have dominated most systems, portfolio optimization sorted technologies into categories such as baseload, load-following, and peaker. What primarily distinguished technologies was the tradeoff between fixed costs (mostly capital investment, but for nuclear also fixed operating costs) and variable costs (primarily fuel). For the baseload portion of the load curve which can be served with a high capacity factor, high fixed costs technologies can yield a low average cost of generation. For the peak load portion of the load curve, which can only be served with a low capacity factor, low fixed cost technologies yield a lower average cost of generation. The optimal mix of different types of technologies is determined by the shape of the load curve and the set of fixed and variable costs across technologies.

The introduction of renewables into the set of available technologies brings in a new factor: the annual profile of renewable resource availability. It is no longer enough to focus on the load curve itself. It is now necessary to appreciate the interaction between the load curve and resource availability. Expanding investments in renewables adds a high volume of generation to some hours of the day and year, but not others. While the dramatic drop in costs have made wind and solar PV the economic choice for incremental investment, as penetration expands the value of additional investment falls because it is not serving load in the most deficient hours. Other technologies are required to serve these hours, or to store renewable generation and deliver it to these hours. The growth in intermittent renewables forces us to move from the old taxonomy of baseload/load following/peaker, to a new portfolio paradigm proposed by Sepulveda et al. (2018) in which resources like nuclear compete as “firm” low-carbon resources complementing intermittent renewables. Jenkins et al. (2018) survey a variety of studies on deep decarbonization pathways and identify this role as a critical one. Our implementation of GenX addresses this issue and brings out the opportunity for nuclear and the challenge of cost.

Full details on the cost assumptions are available in the MIT study report, however, a couple of key figures are useful to call out here. The nominal or base case assumption for the overnight capital cost of nuclear in the two US regions for 2050 is set at \$5500/kW in 2014 dollars. A widely used metric for benchmarking the costs of alternative generation technologies is the Levelized Cost of Electricity (LCOE), so we can concisely describe our assumptions by translating them into an LCOE. Assuming the nuclear plant operates at a 90% capacity factor, our assumptions on the cost of nuclear translate into an LCOE of just over \$100/MWh. In contrast, assuming capacity factors for wind and solar of 34% and 25%, which are in the neighborhood of the available resource factors across our US regions, our assumptions on the cost of wind and solar PV translate into LCOEs of \$72/MWh and \$52/MWh. So nuclear is an expensive alternative in our US regions from the viewpoint of an average unit of generation. Of course, as mentioned above and as will be apparent in the results below, it may be a valuable part of a portfolio because of its capability to generate in hours when the renewable technologies are less available.

The results reported below also consider a case in which the capital cost for nuclear is decreased by 25% to \$4100/kW in 2014 dollars. Where the base case US capital cost assumptions for nuclear are high relative to the cost of other technologies, our assumption for China is markedly lower, at \$2800/kW in 2014 dollars, based on a comparison of US and China costs reported by International Energy Agency (2015). The study contains a number of sensitivity analyses on various other parameters such as the cost of storage.

Fig. 1, below, shows the optimal builds of new nuclear capacity in the New England region depending upon the level of decarbonization targeted and upon the assumed cost of a nuclear plant. The blue bars show the results for the nominal case assumptions. Given the high cost assumed for nuclear and the quality of renewable resources in New England, significant emission reductions are accomplished without nuclear: both the 100 and the 50 g-CO₂/kWh carbon intensity targets are achieved at lowest cost without any nuclear capacity. However, pursuing deep decarbonization brings nuclear into the optimal mix. Given a peak demand of approximately 34 GW, at the deep decarbonization levels the optimal capacity jumps to the neighborhood of 17 GW, which would be a dramatic increase for this one region of the United States.

Fig. 1 shows that for deep decarbonization (10–1 g CO₂/kWh) nuclear is essential to achieve that goal. Fig. 1 also shows that lowering the cost of nuclear makes a dramatic difference to the scale of nuclear. It is a potentially valuable player in Low C, but cost becomes a determining factor to scale.

Fig. 2, below, reports the average generation cost at each decarbonization target and for different assumptions about nuclear. In all cases, costs increase as the target for carbon intensity becomes tighter. The red bars show the impact on costs of excluding nuclear from the mix.

Fig. 1 Nuclear installed capacity in New England as a result of economic optimization for meeting alternative CO₂ reduction targets.

Fig. 2 Average system cost of electricity in New England for each decarbonization target and across three scenarios for nuclear.

Figs. 3 and 4 show these results for the Tianjin, Beijing and Tangshan (T-B-T) region of China where the renewable resources are poorer and the relative cost of nuclear is smaller. Consequently, nuclear is a part of the optimal mix even when targeting modest emission reductions.

Fig. 4 shows that excluding nuclear is very expensive in terms of climate change mitigation. What the GenX analysis shows is that the use of nuclear energy in regions and nations is regionally dependent which one would assume given the variability of solar and wind as well as the costs to deploy the technologies.

Industrial strategy to reduce the cost of nuclear power

In western Europe and the United States, a string of new nuclear plant construction projects have suffered severe construction delays and cost escalations. These include the projects at Olkiluoto, Finland, Flamanville, France, Hinkley Point C, United Kingdom, and the Vogtle and Summer projects in the United States. The cost overruns at Vogtle caused the reactor supplier Westinghouse to declare bankruptcy, and at Summer they eventually led to the project being abandoned midway. In all of these cases, the ultimate cost proved to be far above the nominal cost used in the analysis above, not to speak of the low-cost case. It must be said, however, that many nuclear plant construction projects in South Korea, China, Russia, and the United Arab Emirates have been completed more or less on time, and likely at significantly lower cost than comparable projects in the West, although it is often challenging to

Nuclear Installed Capacity in the Tianjin, Beijing and Tangshan (T-B-T) Region of China as a Result of Economic Optimization for Meeting Alternative CO₂ Reduction Targets

independently validate cost figures published for those projects. Since reducing the capital cost of new nuclear power plants is an existential issue for the nuclear industry and for the pathways to decarbonization, our study made a detailed investigation into the drivers of cost and developed detailed recommendations about how to reduce cost.

The equipment for the reactor and the nuclear steam supply system (NSSS) represents a small share of the total capital cost of a new reactor, as does the equipment for the power island—typically less than 20% in total. The majority of plant costs are in the site preparation, civil works, equipment installation, and project engineering. It is also in these categories where many projects experience large delays and cost overruns. The duration of construction also adds an enormous financing cost. Therefore, cost reduction efforts need to be focused not on the NSSS design or the specific reactor technology but on (a) improvements in how the overall plant is constructed (or delivered to the site), and (b) ways to accelerate the construction process.

Opportunities exist to significantly reduce the capital cost and shorten the construction schedule for new nuclear power plants. First, the deployment of multiple, standardized units, especially at a single site, affords considerable learning from the construction of each unit. In the United States and Europe, where productivity at construction sites has been low, we also recommend expanded use of factory production to take advantage of the manufacturing sector's higher productivity when it comes to turning out complex systems, structures, and components. The use of an array of cross-cutting technologies, including modular construction in factories and shipyards, advanced concrete solutions (e.g., steel-plate composites, high-strength reinforcement steel, ultra-high performance concrete), seismic isolation technology, and advanced plant layouts (e.g., embedment, offshore siting), could have positive impacts on the cost and schedule of new nuclear power plant construction. For less complex systems, structures, and components, or at sites where construction productivity is high (as in Asia), conventional approaches may be the lowest cost option.

It is important to emphasize the broad applicability of these recommendations across all reactor concepts and designs. Cost-cutting opportunities are pertinent to evolutionary Generation-III LWRs, small modular reactors (SMRs), and Generation-IV reactors. The converse is true as well: Without design standardization and innovations in construction approaches, we do not believe the inherent technological features of any of the advanced reactors will produce the level of cost reductions needed to make nuclear electricity competitive with other generation options. The challenge for any proposed plant design is to achieve the radical cost reductions needed to make a new nuclear plant competitive in the on-grid electricity market.

In addition, a continued shift toward reactor designs that incorporate inherent and passive safety features can further reduce the probability a severe accident occurs while mitigating the offsite consequences in the event an accident does occur, and can ease the licensing of new plants and accelerate their deployment in developed and developing countries. These include core materials that have high chemical and physical stability, high heat capacity, negative reactivity feedbacks, and high retention of fission products, together with engineered safety systems that require limited or no emergency AC power and minimal external intervention, will likely make operations simpler and more tolerable to human errors. Such design evolution has already occurred in some Generation-III LWRs and is exhibited in new plants built in China, Russia, and the United States. Advanced reactors like LWR-based SMRs (e.g., NuScale) and mature Generation-IV reactor concepts (e.g., high-temperature gas reactors and sodium-cooled fast reactors) also possess such features and are now ready for commercial deployment. The first commercial high temperature pebble bed gas reactor is scheduled of operation in China in 2020.

Government policy

Government policy can facilitate nuclear power making a valuable contribution to decarbonization. First, decarbonization policies need to create a level playing field that allows all low-carbon generation technologies to compete on their merits. Existing nuclear

power plants are usually a cost-efficient source of low carbon electricity, even when building a new plant might not be. Nevertheless, in a number of markets, supports for low-carbon generation exclude nuclear and alter market prices so that these cost-efficient plants are made unprofitable. Several have closed already and others may close soon. Elsewhere, the policies more directly target closures. Premature closures of existing plants undermine efforts to reduce carbon dioxide and other power sector emissions and increase the cost of achieving emission reduction targets. Fixing these policies is not just relevant for existing plants. It is also necessary to properly incentivize innovations in nuclear energy technology and investments in future new builds of nuclear plants where appropriate. Investors pursuing new, truly low-cost nuclear designs must see the possibility of earning a fair profit based on selling their products for their full value, including the social value of providing low-carbon generation. Current policies that disregard the social value of nuclear energy's contribution to climate change mitigation reduce the prospect for profit and discourage investments in nuclear innovation.

Second, there are direct ways for governments to enable and support development of new, cost-efficient reactor designs. In our report, we recommend that governments should establish reactor sites where companies can deploy prototype reactors for testing and operation oriented to regulatory licensing. Such sites should be open to diverse reactor concepts chosen by the companies that are interested in testing prototypes. The government should provide appropriate supervision and support—including safety protocols, infrastructure, environmental approvals, and fuel-cycle services—and should also be directly involved with all testing. We also recommend that governments should establish funding programs around prototype testing and commercial deployment of advanced reactor designs using four levers: (a) funding to share regulatory licensing costs, (b) funding to share research and development costs, (c) funding for the achievement of specific technical milestones, and (d) funding for production credits to reward successful demonstration of new designs.

Conclusion

Nuclear power has a vital role to play in simultaneously expanding energy access while decarbonizing generation. Its ability to provide firm, low-carbon electricity is a complement to variable renewable generation like wind and solar PV. However, in the United States and Western Europe, the high cost of constructing new plants is a major obstacle to an expanded role for nuclear power. This makes decarbonization more expensive and limits energy access. There are important advances that have been made in a variety of non-nuclear technologies that can be employed in the construction of nuclear power plants to significantly reduce the cost of construction. These cross-cutting technologies can be employed across various reactor concepts and designs, and it is the effective application of these technologies that is likely to be the determining factor in cost reduction rather than the choice of reactor concept. Government policy has a role to play in encouraging and facilitating these innovations and cost reductions. Carbon policy needs to recognize the low-carbon value of nuclear generation alongside other low-carbon technologies in order that nuclear investments can be profitable. Governments can also support innovation by creating facilities where prototypes of new designs can be built and their operation demonstrated.

Introduction

The issue of climate change has faced the environmental community with a difficult dilemma as it relates to the use of nuclear energy. On the one hand, nuclear energy is demonstrably reducing CO₂ emissions. On the other hand, most environmental organizations have opposed the use of nuclear energy for safety reasons and concerns about nuclear waste disposal (Daily Caller, 2015). At present, worldwide there are over 400 operating nuclear plants producing 10% of world's electricity without emission of greenhouse gases. In some countries the proportion of nuclear generated electricity is much larger. For example France produces 72% of its electricity from nuclear energy. Other surprising countries and their nuclear contributions are: Switzerland (38%), Finland (32%), Sweden (40%), United States (19%), Ukraine (56%). In all 440 nuclear plants are deployed in the world with 55 under construction.

It has been estimated that in 2018 these nuclear plants have avoided the release of 60,000,000,000 tonnes of CO₂. Nuclear is the largest base load source of clean energy in the world. While the environmental community recognizes this fact, they are still unwilling to lend their support to their continued operation and further expansion to help reduce CO₂ emissions. Their hope is that through conservation, use of solar and wind energy, taking the “nuclear risk” is not needed (Follett, 2015). These hopes do not reflect the fact that the use of variable energy sources such as wind and solar cannot reliably supply clean electricity on a 24 h per day, 365 days per year operation without massive investment in either energy storage and/or nuclear power reactors. Nuclear energy can make clean electricity on a scale needed to make a difference in combating climate change with wind and solar energy. What would be a desirable outcome is for the environmental community to actively support the expansion of safe nuclear plants in addition to solar, wind, and other renewable sources of energy.

The objective of this article is to highlight reasons for why the environmental community is opposed to nuclear energy; summarize the positions of key national and international environmental organizations; review reasons why some key environmental opinion leaders have changed their positions to become more supportive of nuclear; summarize why some environmental organization support nuclear and finally make the case for why all people, especially those in the environmental community should

support nuclear energy. We conclude that evidence shows that without nuclear energy, in combination with renewables, worldwide success in dealing with climate change is in jeopardy and will be much more costly.

Who and What is the “Environmental Community”

The “Environmental Community” is a self identified group of like minded people who believe their mission is to protect the environment as they see it from human activities. Their mission is narrowly focused on environmental issues typically without regard to the benefits that the human activity may provide. They rarely consider the likelihood of the risks posed but are rather absolutist in their positions. These groups raise funds from people who believe in their causes and use events that may arise in their fund raising campaigns many times exaggerating claims of damage to encourage more funding. Huge contributors to these organizations are green-leaning philanthropies. Grants from 2011 to 2015 totaled close to \$ 500 million none of which supported the development of nuclear energy. \$175,000 was actually dedicated to opposing nuclear energy. (Bryce, 2018). Many of the supporters of these groups do not have a full understanding of the issues but support the groups based on a perceived environmental good. Some groups get government grants to support some of their activities. While their goals are laudable, they, at times, do not consider the totality of the impact of their efforts and may cause negative reaction by the public to overly aggressive actions or dramatic claims.

The leadership of these organizations are typically well versed in the sciences and technology supported by a board of directors with highly regarded reputations. The challenge for the leadership is that should they take a contrary but correct position on an environmental issue that their supporters who are not as well informed but are committed to a position, will stop funding the organization. This is a main impediment to changing views of environmental groups to issues such as support of nuclear energy. In an era of dramatic climate change where constructive action is needed to make a difference according to their own positions, it is imperative that the leadership of these groups begin an education campaign on all energy options available including nuclear to enable the outcomes they seek.

Positions of key environmental groups

World Wildlife Fund

The best summary of why environmental groups oppose nuclear energy is a position statement issued by the World Wildlife Fund in May 2003 (World Wildlife Fund, 2003). Their position summarized below:

While the WWF's priority is to “accelerate implementation of solutions to combat global warming,” they oppose the use of one of the largest clean air electricity sources used today, namely nuclear energy. They do so because they incorrectly assume it is “not sustainable.” The reasons for this belief in their words are:

- “The entire commercial chain of the processing of nuclear raw materials from nuclear mining; operating nuclear power stations; handling nuclear waste and finally re-processing, is full of leaks contamination and produces a highly toxic legacy for thousands of years to come.
- The creation and handling of highly toxic nuclear products and the unsolved issue of safe storage of waste demonstrates the unsustainability of the technology.”

Kadak (2021) and Greneche (2021) adequately address the fallacy of their position however they cite other reasons such as the technology is particularly dangerous and hard to control as the accidents at Three Mile Island (1979), Chernobyl (1986) and Fukushima (2011) demonstrate. These accidents are discussed on other sections of this encyclopedia. Two of these nuclear accidents occurred from 25 to 40 years ago with the more recent Fukushima accident caused by a tsunami not any technical fault of the reactors. They also argue that investments in nuclear energy take funding away from other renewable energy sources which are lower cost. Parsons (2020) explains the deep decarbonization is only possible with a strong mix of nuclear and other renewable energy sources and would be much more expensive to implement even with the higher cost of nuclear plant construction. They also ignore the value of nuclear heat in process heat applications such as desalination of water.

What is unfortunate, nuclear energy plants are a quantifiable source of non-CO₂ electricity saving on a world wide basis 60,000,000,000 tonnes of CO₂ emissions per year which are threatened by the lack of the environmental movement's active support. The electricity generated by nuclear energy plants will be very difficult to replace with variable solar and wind energy plants.

Despite these obvious facts, their anti-nuclear views are shared by many of the other environmental organizations as summarized below.

Sierra Club

The Sierra Club maintains its historical anti-nuclear position based on the three nuclear accidents they refer to as “disasters.” They point out that the Fukushima tsunami which caused the death of more than 20,000 people none of which were caused by the nuclear plant as evidence that the fundamental problems of nuclear power have not been addressed (Sierra Club, 2020) (<https://www.sierraclub.org/nuclear-free>).

Natural Resources Defense Council (NRDC)

Although the NRDC recognizes the “magnitude and urgency” of climate change and the US must consider all forms of energy, they reject nuclear power since it suffers from “too many security, safety and environmental problems.” They also point out that the costs are high while ignoring the high cost of solar and wind alternatives (Cochrane et al., 2005) (<https://www.nrdc.org/sites/default/files/power.pdf>).

Greenpeace (US and Europe)

The Greenpeace organization claims that nuclear energy is expensive and dangerous and poses a risk of a nuclear meltdown. They reject the evidence of nuclear's clean energy contribution today while emphasizing the risks and ignoring the benefits. It is interesting to note that they, as have others in the anti-nuclear community are now using nuclear energy's relatively high cost compared to natural gas as a reason for excluding nuclear. They are, however, willing to pay the high price of solar and wind energy (Greenpeace, 2020) (<https://www.greenpeace.org/usa/global-warming/issues/nuclear/>).

Union of Concerned Scientists

What is most interesting is that of all the historically anti-nuclear groups, the Union of Concerned Scientists has recognized the importance of nuclear energy to combat the global impacts of climate change. In their most recent report on the subject “The Nuclear Power Dilemma: Declining Profits, Plant Closures, and the Threat of Rising Carbon Emissions,” they support a national carbon price or low carbon electricity standard that would help avoid premature shutdown of existing nuclear plants. They suggest that such a carbon price policy would help the USA meet its commitment under the Paris climate agreement (Union of Concerned Scientists, 2015; World Nuclear Association, 2018) (<https://www.ucsusa.org/resources/nuclear-power-global-warming>, <https://www.world-nuclear-news.org/Articles/UCS-calls-for-policy-to-preserve-nuclear>).

Environmental Defense Fund

The position of EDF on nuclear has changed from hostile to neutral finally recognizing that it is indeed a clean energy source. They have recognized that prematurely shutting down existing nuclear plants will result in more CO₂ emissions since they will be replaced with natural gas plants since they are cheaper than solar or wind. They grudgingly support subsidies to keep existing plants open until renewable are cheaper. They do not appear to support the construction of new nuclear plants but they do not oppose them either (Environmental Defense Fund, 2017; Finnigan, 2017) (https://www.edf.org/sites/default/files/content/Clean_energy_fact_sheet_Nov_2017.pdf, <http://blogs.edf.org/energyexchange/2017/04/17/why-we-still-need-americas-nuclear-power-plants-at-least-for-now/>).

Example of change agents in the environmental community

Perhaps the most significant change agents were climate scientists Dr. Ken Caldeira, Senior Scientist, Department of Global Ecology, Carnegie Institution, Dr. Kerry Emanuel, Atmospheric Scientist, Massachusetts Institute of Technology, Dr. James Hansen, Climate Scientist, Columbia University Earth Institute, Dr. Tom Wigley, Climate Scientist, University of Adelaide and the National Center for Atmospheric Research. In 2013, they published a letter to the environmental community which is included in the **Appendix A** to this article. This letter called for those in the environmental community who were opposed to nuclear power to “support the development and deployment of safer nuclear power systems as a practical means of addressing the climate change problem.” They fear “that continued opposition to nuclear power threatens humanity's ability to avoid dangerous climate change.”

Their letter recognized some inherent risks of nuclear energy and called for more advanced designs to reduce the risk but they concluded that the risks of nuclear energy are orders of magnitude smaller than the risk of fossil fuels. They conclude that “there is no credible path to climate stabilization that does not include a substantial role for nuclear power” and urges the environmental community to “support the development and deployment of advanced nuclear energy.”

It is not clear whether their letter triggered other prominent people in the environmental community to change their views but a brief list of people who now see nuclear energy as vital to our efforts to combat climate change is listed below: (Brook, 2011).

Anti- to Pro:

George Monbiot (environmental journalist, went anti- to neutral in 2009, pro- in 2011);
Mark Lynas (author of “Six Degrees”, 2008);
Stewart Brand (author of “Whole Earth Catalog”, 2005);
Dick Smith (Australian entrepreneur, 2011);
Ben Heard (eco-consultant, 2010);
Patrick Moore (co-founder of Greenpeace, 2003);
Stephen Tindale (former director of Greenpeace, 2009);
Chris Smith (chairman of the Environment Agency, 2009);
Chris Goodall (Green Party activist and prospective parliamentary candidate, 2009);
Gwyneth Cravens (author, 2007);
Hugh Montefiore (a founder of Friends of the Earth, 2004);
Chicco Testa (Italian politician, 2008);

Ian McEwan (author, 2010);
 Steve Kirsch (US entrepreneur, 2008); [Tony Blair](#) (former UK PM, 2006);
 Al Franken (Democrat Senator and media host, 2011);
 Michael Shellenberger (Activist, Founder of Breakthrough Institute).

Neutral to pro:

James Lovelock (Gaia theory, 2004);
 Bob Hawke (former Australian Prime Minister, 2008);
 Bob Carr (former NSW Premier, 2008);
 Jared Diamond (scientist and author, 2005);
 Jesse Jenkins, (Breakthrough Institute, 2008–2010).

“Can do with 100% renewables” to “nuclear required”:

Jim Hansen (climatologist, 2008);
 Barry Brook (biologist and risk modeller, 2009);
 David Mackay (physicist, maybe, 2008);
 Jeffrey Sachs (economist, 2009).

Anti- to neutral:

Chris Huhne (UK Lib Dem Energy Minister, 2010);
 Paul Ehrlich (conservation biologist, 2010).

There are likely many more as evidence mounts that without nuclear energy, climate change goals will be extremely difficult if not impossible to attain (<https://bravenewclimate.com/2011/04/15/who-has-changed-their-mind/>).

Described in more detail below are people and organization who believe that nuclear energy is vital to dealing with climate change with some reasons these individuals or groups reached this position.

Michael Shellenberger

A key environmental leader who changed his position from anti-nuclear activist to being an advocate is Michael Shellenberger who co-founded the Breakthrough Institute and is a founder of Environmental Progress. In 2008, he was named by Time magazine as one of the “Heroes of the Environment.” His conversion from anti to being pro nuclear was based on several key points:

- Solar and wind are intermittent sources of energy which require back up power.
- The cost of renewable energy is higher than alternatives.
- Life cycle carbon emissions from nuclear are comparable to solar and wind and much lower than natural gas or coal.
- The safety record of nuclear plants is far better than other sources of energy which they are replacing such as coal, oil and natural gas and equivalent to solar and wind including the major accidents experienced over 50 years in nuclear plants ([OECD, 2010](#); [Mackay, 2015](#)).
- British Medical Journal Lancet finds that nuclear power is already the safest way to make electricity compared to 7 million deaths per year from air pollution from fossil plants ([Markandya and Wilkinson, 2007](#)).
- The lack of scientific evidence of health effects from the Chernobyl accident outside of the Soviet Union. He was particularly struck by the finding that there was no increase in cancer even from the cohorts of people who were fighting the fire at the plant and those that cleaned up afterwards.
- Regarding Fukushima, he notes that no one died from radiation exposure but rather 1500 people who did die were the result of the evacuation and stress caused by the accident. This compared to the 20,000 or so who died as a result of the tsunami that engulfed the mainland of Japan ([World Health Organization, 2020](#); [UNSCEAR United Nations, 2014](#)).
- Regarding the issue of nuclear waste, he notes that nuclear waste is the only waste from the production of electricity that is “contained.” He points out that the toxic heavy metals waste from solar plants does not have a plan for their disposal which is 300 times that produced by nuclear energy which will be safely disposed of in a geological repository.
- In terms of weapons proliferation, his review concluded that no nation that started with a commercial nuclear program ever developed nuclear weapons. He contrasts that with North Korea that does not have a nuclear generating plants but does have nuclear weapons.

In his final summary, he concludes that “If Germany hadn’t closed its nuclear plants, its emissions would be 43% lower than it is today. And I think if you care about climate change, that’s at least something that you have to wrestle with, especially in light of some of these facts about the harms and benefits of different energy sources” ([Shellenberger, 2017, 2018, 2019](#)) (<https://www.youtube.com/watch?v=ciStd9Y2ak>, <https://www.forbes.com/sites/michaelshellenberger/2018/05/08/we-dont-need-solar-and-wind-to-save-the-climate-and-its-a-good-thing-too/#2e2846bde4de>, <https://quilllette.com/2019/02/27/why-renewables-cant-save-the-planet/>, https://www.who.int/ionizing_radiation/a_e/fukushima/faqs-fukushima/en/, <https://www.thelancet.com/action/showPdf?pii=S0140-6736%2807%2961253-7>, http://www.unscear.org/docs/publications/2013/UNSCEAR_2013_Report_Vol.I.pdf, <https://www.oecd-nea.org/ndd/reports/2010/nea6861-comparing-risks.pdf>, http://www.inference.org.uk/withouthotair/c24/page_168.shtml).

Breakthrough Institute

The Breakthrough Institute was founded in 2008 by Michael Shellenberger and Ted Norhaus whose visions for the environmental movement were different than those of the past. They believed that to truly deal with climate change a new approach was needed. In 2004, they published an essay entitled "The Death of Environmentalism" which pointed out that "20th century environmentalism cannot address complex global environmental challenges like climate change." Their focus was on making clean energy "cheap" that would not affect global economic development at the expense of addressing climate issues which is needed to address the needs of billions of people trying to live "modern" lives. They call for substantial innovation in energy production to meet these aggressive goals (Breakthrough Institute, 2020).

As an organization, the Breakthrough institute believes that nuclear energy is essential to the clean air revolution. They call for nuclear innovation, (Lovering et al., 2017), identify opportunities to make nuclear energy cheap, (Lovering et al., 2013) and how to "plant the seeds for a nuclear revolution," (Lovering et al., 2018). They conclude that despite impressive shifts in energy production in Germany, California, Denmark and other nations, no large economy has been able to power all of its electric grid with only renewables. They bemoan the fact that despite nuclear energy's clean power, environmental organizations continue to push for their closure making it an illogical argument given their view that climate change is an "untenable threat to human societies." They urge their peers to change their positions based on facts not politics. They recognize that there is a political battle to be won to deploy more nuclear plants but the battle is worth waging for all including environmental groups historically opposed (Nordhaus, 2018; McBride, 2018) (<https://thebreakthrough.org/articles/how-to-make-nuclear-innovative>, <https://thebreakthrough.org/articles/how-to-make-nuclear-cheap>, <https://thebreakthrough.org/articles/planting-the-seeds-of-a-distributed-nuclear-revolution>, <https://thebreakthrough.org/issues/energy/a-new-day-for-nuclear-advocacy-and-environmentalism>, <https://thebreakthrough.org/issues/energy/nuclear-for-1-5-c>).

Conservation Law Foundation

The Conservation Law Foundation was one of the lead organizations seeking to block the construction and operation of the Seabrook nuclear plants in New Hampshire in the 1970s and proudly claims that it helped cancel the second unit at Seabrook. Today, it is concerned that with the tendency to shutdown existing nuclear plants in New England, Yankee Atomic, Vermont Yankee, Maine Yankee, Vermont Yankee and Pilgrim that have already been shutdown. This generation is being replaced with CO₂ and greenhouse gas emitting natural gas plants. As an example, in the 1980s nuclear energy generated about 40% of the electric energy mix. Today 40% is natural gas fired with nuclear's contribution reduced to less than 20%. The Conservation Law Foundation does not support new nuclear construction believing that solar and wind can do the job. They are also actively opposing new natural gas plants and associated pipelines in New England believing in the totally renewable electric grid. They have not actively supported keeping existing nuclear plants operating despite their concern about the loss of this clean energy source.

The pillars of the Conservation Law Foundation are based on three principles which include pushing policies that boost low-cost locally made clean energy; advocating against natural gas expansion in New England; and shutting down the rest of the coal plants. They do call innovative ideas to lessen carbon emissions. They do not identify what those "low-cost locally made clean energy sources are." The policies supported by CLF include increasing the amount of electricity that must be purchased by utilities in renewable portfolio standards, increasing transmission line capacity to handle the distributed solar and wind installations and lifting caps on net metering. They also do not address the major issue of how they will supply power at night or during periods of no wind. Many of these suggestions are disruptive to electric grid operation and raise the cost of electricity. Noticeably absent is any support for existing or new nuclear plants (Conservation Law Foundation, 2020) (<https://www.clf.org/our-focus/climate-change/>).

UN Intergovernmental Panel on Climate Change (https://www.ipcc.ch/site/assets/uploads/sites/2/2019/05/SR15_SPM_version_report_LR.pdf, <https://www.ipcc.ch/sr15/chapter/spm/>)

The October 2018 report of the Intergovernmental Panel on Climate Change identified pathways to reduce climate change temperature increase to 1.5C. The IPCC report outlined several scenarios in which this is possible. All of the scenarios include a major increase in the use of nuclear energy. Of the four major scenarios reviewed shown on Fig. 1 below P1 represents the 1.5° pathway with the least economic and energy growth; P4 the most. According to their estimates which was summarized in a results oriented chart by the Breakthrough Institute, nuclear's share of primary energy doubles by 2030 and quintuples by 2050 in the scenarios with the highest economic growth and energy demand to meet the 1.5C increase limit (International Panel on Climate Change, 2019; International Panel on Climate Change, 2018).

The IPCC report compared nuclear with other low carbon technologies such as wind, solar, biomass and carbon capture and sequestration each of which have significant challenges as reported by the IPCC. They include huge land use commitments, supply of raw materials needed for such distributed low energy density sources compared to nuclear and carbon capture and sequestration. They point out that nuclear energy faces major obstacles in regulation and social acceptance to achieve this large but needed expansion.

International Energy Agency (<https://www.iea.org/reports/nuclear-power-in-a-clean-energy-system>)

The International Energy Agency (IEA) is an intergovernmental organization which is part of the Organization for Economic Cooperation and Development. The IEA was formed to assist nations in dealing with oil and energy issues. It is largely a data collection agency that publishes periodic reports on energy issues and serves as a policy advisor to its member states. They have adopted a three

Fig. 1 IPCC estimates of nuclear in 2030 and 2050.

Fig. 2 Low-carbon electricity generation in advanced economies by source, 1971–2018.

prong area of energy policy for focus: Energy Security, Economic Development, and Environmental Protection. They have a broad role in promoting alternate energy sources, rational energy policies and energy technology cooperation among nations.

The International Energy Agency's recently released report "Nuclear Energy in a Clean Energy System" (International Atomic Energy Agency, 2019) summarizes why nuclear energy must play a role in significant decarbonization. Fig. 2 points out the existing role nuclear energy plays in the clean energy sector from 1971 to 2018. This figure shows that in advanced economies nuclear energy is by far the most abundant source of clean power.

This trend continues in 2018 as shown in Fig. 3 below. Most people may not be aware of this enormous contribution to clean electricity supply.

Shown on Fig. 4 are the country by country savings in carbon dioxide emission avoided. Globally emissions would have been 20% higher without nuclear energy. In absolute terms over 60 Gigatonnes (60,000,000,000 tonnes) would have been emitted in 2018 without nuclear energy. As these figures adequately demonstrate nuclear energy is a proven clean energy source.

This report highlights what is necessary for nuclear to continue to play a productive role in the transition to renewable energy sources. One of the concerns expressed is that with the premature shutdown of existing nuclear plants worldwide, the transition to clean energy has slowed. Additionally, they point out, consistent with IPCC recommendations that to achieve 85% of global electricity coming from clean energy sources such as wind, nuclear and solar it will require an expansion three times the rate currently being deployed by 2040. This trajectory would need an 80% increase in global nuclear power production by 2040. To keep from further retardation of progress, they recommend extending the licenses of operating nuclear plants from 40 to 60 and perhaps even 80 years (as is being done in the US).

As the share of variable renewables increases, nuclear energy will be even more needed to provide grid stability increasing energy security and improving reliability. IEA also points out that often times, markets and regulatory systems do not value nuclear energy's contribution to clean energy and electricity security causing early closures of sound operating plants.

They conclude that without nuclear energy plants, achieving a sustainable energy system will be much harder to achieve and more costly. They call for intrusive policy making to enable existing nuclear plants to continue to operate and the needed new plants

Nuclear power is the leading low-carbon source of electricity in advanced economies today.

Fig. 3 Low-Carbon electricity generation in advanced economies by source, 2018.

Without nuclear power, global CO₂ emissions from electricity generation would have been almost 20% higher over the last half-century.

Fig. 4 Cumulative CO₂ emissions avoided by global nuclear power to date.

to be built. Their analysis suggests that at least \$ 1.6 Trillion of new investment would be required in the electricity sector from 2018 to 2040. The costs will be even higher if existing nuclear plants' lives were not extended.

MIT Report on decarbonization

In 2018, MIT's Energy Initiative project published "The Future of Nuclear Energy in a Carbon Constrained World" (MIT Energy Initiative, 2018). This report examined many electricity generating options with the goal of maximizing the elimination of carbon and minimizing costs. Their exhaustive report reviewed alternatives including nuclear, solar, wind, natural gas, coal, hydro, battery storage. The options considered are listed below (Table 1).

MIT employed a GenX model which optimizes the cost of electricity for a given carbon limit target. For a given power market the required inputs include hourly electricity demand, hourly weather patterns, economic costs (capital, operations, and fuel) for all power plants (nuclear, wind and solar with battery storage, fossil with and without carbon capture and storage), and their ramp-up rates. The GenX simulations were used to identify the electrical system generation mix that minimizes average system electricity costs in each of these markets to identified CO₂ targets.

The goal is to find out the optimal cost effective mix that achieves the carbon targets. These targets are quantified as gm-CO₂ emissions per kilowatt-hours (kWh) of power produced for the optimal economic mix. The targets chosen were 500 (the current carbon density), 100, 50, 10, and 1 g-CO₂/kWh. For nuclear energy they modeled five scenarios for each target to see what the economic model would predict—no nuclear, high cost, nominal cost, low cost and extremely low cost. For the low and extremely low cost, the assumption was that they were 25% and 50% respectively lower than the nominal in the region. The high cost was assumed to be 25% higher than nominal.

Table 1 Technology options for each pathway.

<i>Nuclear Energy Is An Allowed Option</i>	<i>Nuclear Energy Is NOT An Allowed Option</i>
<i>Carbon-Free Options</i>	
Photovoltaic (PV) Solar	PV Solar
On-shore Wind	On-shore Wind
Light-water Reactor (LWR) Nuclear	Coal with CCS (IGCT-CCS)
Coal with Carbon Capture and Storage (CCS)	Natural Gas with CCS
Natural Gas with CCS

Open Cycle Gas Turbine (OCGT)	OCGT
Combined Cycle Gas Turbine (CCGT)	CCGT
Coal (IGCC)	Coal (IGCC)
<i>Storage Options</i>	
Battery Storage	Battery Storage
Hydro-electric Storage (Fixed)	Hydro-electric Storage (Fixed)

**Fig. 5** New England cost of electricity generation.

They compared several regions. For the US, they chose New England and Texas. For international markets they chose France, the United Kingdom and China (the Tianjin-Beijing-Tangshan (T-B-T) area). The nominal overnight capital cost for nuclear (Rothwell, 2021) in the New England area (US) chosen was \$ 5500/kWe installed in 2050. In China, they are able to build the nuclear plants considerably cheaper and a \$ 2800/kW was assumed. To test the sensitivity of their model to fluctuating prices for alternative energy sources similar variability studies were included which are thoroughly documented in their report.

The results of their optimization model are revealing. Clearly the cost of nuclear energy reflects heavily on the contribution to various emission targets. Figs. 5 and 6 shown below are the results for New England and China.

As can be seen, without nuclear energy, the cost of achieving clean energy targets is much higher for deep decarbonization. For France similar results are shown on Figs. 7 and 8.

It should be pointed out that according to climate change stabilization scenarios developed by the International Energy Agency in 2017, the power-sector carbon intensity targets to limit global average warming to 2 °C range from 10 to 25 g/MWh of CO₂ by 2050 and less than 2 g/MWh by 2060.

The conclusion of the MIT study is that without nuclear energy deep decarbonization, the cost will be higher and targets for limiting CO₂ emissions will be difficult to meet. This finding supports the 2014 UN Intergovernmental Panel on Climate Change which concluded that deep cuts in greenhouse gas emission “will require more intensive use of ... technologies such as renewables [and] nuclear energy.” Additionally in 2015, the International Energy Agency called nuclear power “a critical element in limiting greenhouse gas emissions.” At that time it said that “global nuclear-generation capacity must more than double by 2050 (to about 750 GW) for there to be any hope of limiting temperature increases to the 2-degree scenario that is widely agreed as the acceptable limit.”

Unfortunately, with the exception of China, no other nation is pursuing nuclear energy to the extent needed. To achieve these aggressive targets the MIT report made several recommendations:

1. The need to reduce nuclear energy's cost should be done by improved management, advanced construction and manufacturing including standardization and modularization.

Fig. 6 T-B-T cost of electricity generation.

Fig. 7 United Kingdom cost of electricity generation.

Fig. 8 France cost of electricity generation.

2. Research, design and development to introduce innovative new reactor concepts aimed at reducing capital and operating costs.
3. A more innovative approach to deployment is needed for these advanced concepts to allow for faster demonstration and deployment.
4. There should be no public policies that discriminate against nuclear energy but rather provide a level playing field for all clean energy sources.
5. The government should provide funding to test prototype nuclear plants.
6. The Nuclear Regulatory Commission should move more rapidly to employ risk informed performance based regulatory regime and facilitate the licensing of prototype reactors and funding for their review.

These are just a few of the recommendations found in the MIT report. Their report is rich with findings and other numerous recommendations to enable an important and vital role for nuclear energy in the quest for a real climate change solution and deep decarbonization (<https://energy.mit.edu/wp-content/uploads/2018/09/The-Future-of-Nuclear-Energy-in-a-Carbon-Constrained-World.pdf>).

The environmental case for nuclear energy

As can be seen in the previous sections, the role of nuclear energy in dealing with climate change is very important not only from a reduction in CO₂ but in terms of the affordability of the transition from a fossil based economy to a clean air renewable energy economy. A mix of electricity sources will be required. Nuclear's role will likely be a base load source of power with some ability to follow the load during the day and night. Studies are now being conducted to use nuclear energy when too much solar or wind are put into the grid. These applications include producing water, alternative energy storage systems such as liquid metals, process heat applications for industry and heating or making hydrogen to replace fossil fuels for transportation. These innovations can make nuclear energy even more economical since they can then be run essentially base loaded reducing the cost per kilowatt-hour and these other uses provide income to offset nuclear's relatively higher capital cost.

As an example of how an integrated energy system using nuclear generated heat can be applied with renewable energy systems is shown on Fig. 9 (Hezlar, 2021). The nuclear plant shown on the left can be combined with industrial applications shown on the right through decoupled energy storage systems (blue and brown storage tanks). This configuration when also coupled with supercritical CO₂ power conversion system enables rapid load following as well. High temperature molten salts can be used as the heat storage and transport system.

What is key to understand is that nuclear energy is one of the cleanest energy sources comparable to that of wind and solar. Nuclear energy is a highly concentrated energy source requiring minimal land or water use compared to wind or solar. It can be integrated with solar and wind if properly managed. Nuclear energy's safety record is very good. The accidents that have occurred were due to bad design (Soviet Union), a poor siting decision (Japan) and poor operator response and design (United States). The 440 reactors operating today in 31 countries are doing so safely and have performed well for over 50 years.

The issue of nuclear waste disposal needs a political consensus. Technically all nations agree that geological disposal is the safest alternative. In the United States, Yucca Mountain had completed its technical review finding that the facility could be safely build, operated and then sealed for hundreds of thousands of years but the US government chose to stop the project based on political, not technical reasons. Other countries such as Finland and Sweden are making great progress in actually building a repository. France, United Kingdom, Germany, China, and Japan are investigating suitable geological sites. Some nations are pursuing recycling of used nuclear fuel. France and the United Kingdom are reprocessing the used fuel to reduce the volume of waste needing disposal (which is very small in any case). France is making new fuel from the recycled product and making additional electricity. Advanced reactor designs using waste from enrichment plants can be used to make more fuel in sodium cooled fast breeder reactors essentially extending our uranium supplies for thousands of years without additional mining.

The opportunities nuclear energy offers to the world are enormous. Nuclear energy can be safely operated, advanced reactors with inherently safe design features, small modular reactors allowing for distributed electricity sources, clean water, process heat

Fig. 9 An example of an integrated energy system with nuclear power.

applications as well as a clean way to make hydrogen for the next generation for transportation fuels are but a few examples. Should we move to electric vehicles, more electricity will be required for the world in its continuing quest for a clean environment.

While solar and wind are often referred to as “renewable” sources of energy, nuclear power can also be considered as renewable in the sense that the fuel, uranium, currently already mined and in seawater is almost an infinite supply. In the uranium enrichment process, U-238 contained in residual mill tailings when used in fast breeder reactors can provide thousands of years of electric power. Additionally, even though the amount of natural uranium dissolved in seawater is very low (parts per billion), new techniques for extracting uranium are becoming available. This could essentially be an infinite supply should it be needed.

Unfortunately nuclear energy's potential is limited by the social and political aspects of the technology as pointed out by the IPCC. The lack of active support from the environmental community believing that solar and wind can do it all affects the social and political support needed for nuclear energy to continue to contribute. Studies already described earlier disprove that unfortunate assumption that solar and wind can do it all. Many opinion leaders have already lead the way for others to follow. The mistakes of Germany, in their shutting down their nuclear plants, in the hopes of reducing their carbon emissions has not worked (Energiewende program) and the costs to consumers has gone up significantly. The social cost of the phase out has been over \$ 12 billion in terms of increased health costs due to air pollution due to increased coal and gas usage to replace the nuclear capacity. Additionally in 2107, Germany spent \$ 26 billion Euros in transition costs alone—all borne by industry, taxpayers and consumers. In all, Germany has spent over \$ 400 billion on renewables with not much to show for it in terms of CO₂ reductions (Jarvis et al., 2020) (<https://haas.berkeley.edu/wp-content/uploads/WP304.pdf>).

A example of where a reduction in carbon emission strategies have worked can be found in France and Sweden. While this chart is relatively old it does show the effect of a strong nuclear energy program on the lowering of CO₂ emissions compared to Denmark which is an anti-nuclear country and China which at that time was heavily dependent on coal. Since 1990 China has embarked on an aggressive nuclear power expansion program with 46 nuclear plants in operation and 11 under construction.

Fig. 10, taken from Goldstein and Qvist (Goldstein and Qvist, 2019) shows future global emission intensity if the world transitions to clean energy like Germany did in its Energiewende program versus if the world builds nuclear power plants at a rate comparable to that done by France and Sweden during the global oil crisis in the early 1970s. It confirms studies of the IPCC and others that nuclear energy can play a most significant role in decarbonization of the planet.

A summary of the key reasons to support nuclear energy are provided below.

Intermittency of renewables

The technical reality of solar is that it is an intermittent source of electricity. The best solar farms produce electricity about 25% of the time which means that in a truly renewable economy, batteries or alternative energy sources like diesel-generators will be needed for 75% of the power. Unfortunately such battery technologies are not available so back up sources such as nuclear will be needed.

Wind can do a better job, depending on location. Denmark is a great example. There were days in 2018 when wind supplied all of Denmark's power, but as we all know, wind does not blow all the time. In fact for the full year, wind produced only 50% of Denmark's electricity demand. Denmark was lucky to have been able to fill the gap from imported power from other countries, most likely France's nuclear fleet or fossil plants elsewhere on the grid. The bottom line for even Denmark, they will need back up power for over 50% of the time. This is certainly an untenable position if all Europe gets rid of its nuclear or fossil plants.

As an example, Michael Shellenberger uses the example of how an activist believed that solar could replace the Palo Verde nuclear plants in Arizona. These nuclear plants generate 4000 MW of power on a 24/7 basis. It supplies over 1/3 of Arizona's electricity needs. He calculates that for a week of cloudy weather which sunny Arizona gets from time to time, it would take 670 GW of battery capacity. He found that the total battery storage available in the United States at the end of 2019 is about 3 GW. This

Fig. 10 CO₂ emissions from nuclear and non-nuclear countries.

includes all the batteries found in utilities, homes and cars. What these numbers mean is that to replace this one plant, one would need 200 times the available battery capacity in the US. While technology development is ongoing, the scale needed is enormous. The largest current battery in the world is a 126 Mw Tesla battery being used in Australia which cost \$ 66 million. To replace the Palo Verde plant, one would need 5000 of them having a total cost of \$330,000,000,000! The limitation of solar and wind requiring back up power should not be dismissed since at scale, it cannot be a solution.

Life cycle emissions of energy sources (http://www.world-nuclear.org/uploadedFiles/org/WNA/Publications/Working_Group_Reports/comparison_of_lifecycle.pdf)

The World Nuclear Association compiled research papers and reports from numerous sources reviewing the life cycle emissions from all sources of electric energy production. Reports from 21 sources were compiled and analyzed (World Nuclear Association, 2011). Shown on Fig. 11 are the sources used in this analysis.

Their summary report "Comparison of Lifecycle Greenhouse Gas Emissions of Various Electricity Generation Sources" provides the following results as shown on Table 2.

Graphically the results can be presented as shown on Fig. 12 with uncertainty ranges indicated in the estimates by the research reports.

These results show unquestionably that nuclear energy is a very low source of greenhouse gas emissions comparable to wind and solar and other so called "renewable" electric generating sources. The highly reputable Lancet journal seems to agree according their quote "Nuclear power has one of the lowest levels of greenhouse-gas emissions per unit power production and one of the smallest levels of direct health effects "and they add" it would add a substantial further barrier to the achievement of urgent reductions in greenhouse gases if the current 17 percent of world electricity generation from nuclear power were allowed to decline" (Markandya and Wilkinson, 2007) ([https://www.thelancet.com/article/S0140-6736\(07\)61253-7/fulltext](https://www.thelancet.com/article/S0140-6736(07)61253-7/fulltext)).

Land use

In 2017, a comparative study of land use of electricity production sources was performed by Strata, a non-government research organization that conducts scholarly research and analysis on a variety of public policy issues. Their papers are designed to influence and inform policy makers, citizens and civic leaders. One of their reports focuses on land use of alternative energy systems entitled "The Footprint of Energy: Land use of U.S. Electricity Production" (Stevens et al., 2017).

Their analysis includes direct and indirect land requirements for coal, natural gas, solar, nuclear, hydro and wind generating systems. Included were land required for mining, transport, transmission and waste storage. See Fig. 13. Due to the high energy density of coal, natural gas and nuclear energy, they have the smallest physical footprint of about 12 acres/MW produced. The highest land use commitment was hydro at 315.2 acres/MWe. Solar was found to be 43.5 and wind at 70.6 acres/MWe. According to a study done by Entergy Arkansas to replace the energy produced by their Arkansas One Nuclear station which generates 1800 MWe takes up 1100 acres (1.7 mile²). To replace that amount of power would require 108,000 acres (169 mile²) for wind and 13,200 acres (21 mile²) for solar (Fig. 14).

Thus the land commitment for renewables is huge for renewables which also creates other environmental impacts. For the CO₂ reduction benefit nuclear energy is a clear winner in terms of land use (<https://www.strata.org/pdf/2017/footprints-full.pdf>).

Fig. 11 Comparison of Future World Carbon Intensity under German Energy Strategies.

Table 2 Summary of GHG Lifecycle Emission Intensity From Various Sources.

Technology	Mean	Low	High
	tonnes CO ₂ e/GWh		
Lignite	1054	790	1372
Coal	888	756	1310
Oil	733	547	935
Natural Gas	499	362	891
Solar PV	85	13	731
Biomass	45	10	101
Nuclear	29	2	130
Hydroelectric	26	2	237
Wind	26	6	124

**Fig. 12** Summary of the number of literature sources cited for each generation method.

Cogeneration

To improve the competitiveness of nuclear and to better utilize nuclear energy in an era of increasing solar and wind systems on the electric grid, Dr. Charles Forsberg of the Massachusetts Institute of Technology organized a workshop at MIT to discuss possible options in June 2017 (Forsberg, 2017). The results of the seminar was summarized in a Report entitled "Light Water Reactor Heat Storage for Peak Power and Increased Revenue: Focused Workshop on Near-Term Options." The workshop discussed examples of how nuclear electric plants could be integrated with these renewable sources.

One of the problems has been that during the day, solar plants can contribute significant amounts of power during the day requiring reducing the power of nuclear plants due to grid overload and reducing prices to almost zero and at times negative. Later during the day as the sun sets, the electricity is needed and the price of power increases requiring back up power. At night, these plants may be needed but due to the negative or low prices during the day, they are uneconomic to run since they cannot offset their high capital costs. This mismatch is causing some utilities to prematurely shutdown their plants. To make up the difference, utilities are installing greenhouse gas emitting natural gas turbine plants to provide the needed power which is counter to reducing CO₂ emissions.

In order to maintain a base load capability for this plants, i.e., having the nuclear plant operate 24 h a day at full power, options have been proposed to utilize the steam produced instead of electricity generated. The goal is to bypass the electric generator when prices are low and when prices are high during the day, reconnect the generator to produce electricity. When the steam turbine is bypassed, the steam would be sent to other industrial operations that need the steam, steam storage systems to include steam accumulators (tanks), sensible heat storage, cryogenic air storage, packed pebble beds heat storage, hot rock storage, and geothermal storage.

Fig. 13 Life cycle GHG emission intensity of electricity generation methods.

Fig. 14 Comparative land use of energy options.

The value of such systems are dependent on the market economics that would justify whatever investments might be required to offset the energy savings. Some of these technologies have been deployed on a limited basis but others require more development. Regulatory approvals might be required to utilize nuclear heat in these applications but one US utility has shown the selling steam to a local industry would be acceptable. Other countries use low grade heat coming from nuclear power stations to provide district heating (Russia) and Germany has used similar heat to warm soils to allow for longer growing seasons.

Another application that would be welcome is that of making fresh water from salt water in countries where water resources are scarce. This can be done by reverse osmosis (using electricity) or desalinization using the evaporative process. Some have also

suggested that the electricity could be used to make hydrogen for fuel cells or using it to convert CO₂ in the air to make hydro-carbon fuels for transportation. Hydrogen can also be made using electricity in a water separation process.

Thus, there are many compatible applications to use nuclear's excess electricity and unused heat to integrate nuclear energy in a renewable economy (<https://energy.mit.edu/wp-content/uploads/2017/12/Light-Water-Reactor-Heat-Storage-for-Peak-Power-and-Increased-Revenue.pdf>).

Advanced reactors

Today, there are more than 55 advanced reactor concepts under development world wide. These include micro-reactors of several Kilowatts to megawatt sized plants for distributed applications. Many small modular reactors (SMR) that are under development to address the concern about the total cost of large 1000 MW sized reactors; they offer significantly lower financing risk and inherent safety in which basic laws of physics protect against accidents involving emission of radioactive effluents without human intervention even in case of loss of power (Ingersoll, 2021). The SMR market targets distributed electricity avoiding the need to build large transmission system to support the larger plants. Other new nuclear technologies under development include nuclear plants using liquid metal coolants, helium gas, molten salts and heat pipe designs. All have technological features that greatly reduce the risk of accidents and have inherently safe designs that all but eliminate the possibility of a reactor meltdown scenario so feared by many; significantly higher efficiency for converting fission energy to electricity; up to two order of magnitude improvement in uranium utilization and significant reduction in the volume and toxicity of the nuclear waste. A complete discussion of advanced reactor concepts is found in Section "Example of change agents in the environmental community" of this article.

The summary of the case for nuclear energy

- Solar and wind energy are dilute source of energy. To produce the 4.4 Terrwatts of power the US will require in 2050 will mean covering 300,000 km² with solar panels and 1.5 million km² with wind farms for balanced wind production. This is about 20% of the total land area of the US.
- Solar and wind consume a great deal of material for manufacture of the panels and turbines some of which are toxic. To build an all renewable grid by 2050 which is a goal of some, will require about 200 million tonnes of glass, aluminum and steel, all of which are energy intensive.
- Solar will require extensive amounts of cadmium and tellurium both of which are toxic and relatively rare. Present known reserves of tellurium are about 20,000 tonnes. These reserves will have to increase by 1500 times to supply the tellurium needed for a 2050 transition to an all solar and wind economy. This might require deep sea mining with its ecological impacts which will increase costs for solar.
- For massive solar and wind installations, they will likely be centralized in massive solar and wind farms located in relatively rural areas. This will necessitate considerable grid expansion since existing nuclear and fossil plants are not located in such areas. The reliability of such long distance grids is questionable as are the losses in transmission of power over such long distances.
- There is currently no feasible means to provide the back up power needed in during periods of no sun or wind. Natural gas is the solution being deployed in large amounts which contributes to the release of CO₂ and other greenhouse gases and penalizes the economics of the solar/wind electricity generation.
- Nuclear energy is a proven performer providing clean CO₂ free electricity on a massive scale which is scalable to meet world energy needs.
- The current challenge for nuclear energy is competing with subsidized renewable energy and cheap natural gas which is a major CO₂ emitter.
- Advanced nuclear plants will be built with more enhanced safety features than already highly safe operating reactors that supply more than 10% of the world's electricity.
- To meet aggressive climate change goals, nuclear and other clean energy sources will have to massively be expanded in addition to keeping existing nuclear plants operating.
- The most significant public objection to nuclear energy is waste disposal. Scientists all agree that geological disposal is the proper solution but it is being hampered by political opposition. With political leadership such as that found in Finland and Sweden, the solutions are being implemented.

(LLP Fusion, 2020; National Renewal Energy Laboratory, 2013; US Energy Information Agency Administration, 2019; Energy Efficiency and Renewable Energy, 2019) (<https://lppfusion.com/environment/why-solar-and-wind-cant-replace-fossil-fuels-by-themselves>, <https://www.nrel.gov/news/press/2013/2269.html>, https://www.eia.gov/energyexplained/?page=us_energy_home, <http://css.umich.edu/factsheets/us-cities-factsheet>, <https://www.energy.gov/eere/solar/articles/solar-plus-storage-101>).

Will the real environmentalists please stand up

Given the global challenge that these groups have identified and call for "dramatic action," it is time for them to address their dilemma. They need to confront their objections and rationally conclude that nuclear energy is a part of the solution. They need not only to accept the science of climate change but also the science of practical solutions overcoming their historical opposition to nuclear energy. As existing nuclear plants are being prematurely shutdown due to economic, not safety reasons, it is time to act before we lose more clean energy plants that provide a huge source of electricity. These plants are shutdown due largely to cheap natural gas and subsidies given to solar and wind, it is time to stand up and politically support not only continued operation and new plant construction with financial support similar to the given to other "clean energy" technologies.

It is time for the leadership of these organizations to embrace nuclear energy as part of the solution to climate change in an integrated electrical system that harnesses the value the nuclear energy offers in reducing CO₂ emissions. This will take bold action by the leaders of environmental organizations and a call to action by helping educate their members about the need and value of nuclear energy. This task will be difficult but important if we are to deal realistically and positively with the global challenge if they really believe that it is an existential threat.

As the climate scientists' letter of 2013 said "continued opposition to nuclear power threatens humanity's ability to avoid dangerous climate change."

Appendix A

MIT Climate Scientists Letter

Shared publicly—Nov 3, 2013

Kerry Emanuel originally shared:

To those influencing environmental policy but opposed to nuclear power:

As climate and energy scientists concerned with global climate change, we are writing to urge you to advocate the development and deployment of safer nuclear energy systems. We appreciate your organization's concern about global warming, and your advocacy of renewable energy. But continued opposition to nuclear power threatens humanity's ability to avoid dangerous climate change.

We call on your organization to support the development and deployment of safer nuclear power systems as a practical means of addressing the climate change problem. Global demand for energy is growing rapidly and must continue to grow to provide the needs of developing economies. At the same time, the need to sharply reduce greenhouse gas emissions is becoming ever clearer. We can only increase energy supply while simultaneously reducing greenhouse gas emissions if new power plants turn away from using the atmosphere as a waste dump.

Renewables like wind and solar and biomass will certainly play roles in a future energy economy, but those energy sources cannot scale up fast enough to deliver cheap and reliable power at the scale the global economy requires. While it may be theoretically possible to stabilize the climate without nuclear power, in the real world there is no credible path to climate stabilization that does not include a substantial role for nuclear power.

We understand that today's nuclear plants are far from perfect. Fortunately, passive safety systems and other advances can make new plants much safer. And modern nuclear technology can reduce proliferation risks and solve the waste disposal problem by burning current waste and using fuel more efficiently. Innovation and economies of scale can make new power plants even cheaper than existing plants. Regardless of these advantages, nuclear needs to be encouraged based on its societal benefits.

Quantitative analyses show that the risks associated with the expanded use of nuclear energy are orders of magnitude smaller than the risks associated with fossil fuels. No energy system is without downsides. We ask only that energy system decisions be based on facts, and not on emotions and biases that do not apply to 21st century nuclear technology.

While there will be no single technological silver bullet, the time has come for those who take the threat of global warming seriously to embrace the development and deployment of safer nuclear power systems as one among several technologies that will be essential to any credible effort to develop an energy system that does not rely on using the atmosphere as a waste dump.

With the planet warming and carbon dioxide emissions rising faster than ever, we cannot afford to turn away from any technology that has the potential to displace a large fraction of our carbon emissions. Much has changed since the 1970s. The time has come for a fresh approach to nuclear power in the 21st century.

We ask you and your organization to demonstrate its real concern about risks from climate damage by calling for the development and deployment of advanced nuclear energy.

Sincerely,

Dr. Ken Caldeira, Senior Scientist, Department of Global Ecology, Carnegie Institution.

Dr. Kerry Emanuel, Atmospheric Scientist, Massachusetts Institute of Technology.

Dr. James Hansen, Climate Scientist, Columbia University Earth Institute.

Dr. Tom Wigley, Climate Scientist, University of Adelaide and the National Center for Atmospheric Research.

Introduction

It is time to mainstream the use of peaceful nuclear technology at the highest level. That means raising public awareness about nuclear technology, incorporating it explicitly into national development plans, and stressing its importance to aid agencies and donors. (Yukiya Amano, IAEA)

Nuclear energy today is derived from the fission of uranium and plutonium in nuclear reactors either to produce heat internally within the reactor or to supply neutrons externally. The internal heat is typically used to make steam which drives turbine generators for electricity, but other applications are possible. The most energy-dense source of heat anywhere is nuclear, and high temperatures are readily achieved. But in contrasting application, the neutrons produced by research reactors are for a variety of applications, most obviously the production of radioisotopes for industry and medicine. Any heat is incidental.¹

Radiation, in the context of this chapter, is ionizing radiation employed for human benefit in a wide range of applications, including industry, agriculture and medicine. Ionizing radiation includes X-rays, which are of atomic rather than nuclear origin.

The International Atomic Energy Agency (IAEA) is the United Nations body overseeing world nuclear energy developments to benefit mankind. Its late Director General, Yukiya Amano, said at the opening of the *IAEA Ministerial Conference on Nuclear Science and Technology: Addressing Current and Emerging Development Challenges* in Vienna in November 2018, “Developing countries are especially interested in how the Agency can help them to grow more food, treat cancer, manage water supplies, protect the oceans and monitor climate change. However, I find that such awareness is often limited to the nuclear community—the scientists, engineers and doctors working in the field. At national level, there is often a lack of awareness of the major contribution nuclear science and technology make to development. As a result, the full potential of peaceful nuclear science and technology is not being realised.”

¹Some radioisotopes are also produced in certain power reactors, incidentally.

Electricity

By far the major application of nuclear energy is for generating electricity on a large scale without any CO₂ or other greenhouse gas emissions. Nuclear power avoids the emission of about 2 billion tonnes of CO₂ per year, relative to coal, and it could do much more.

Over 10% of the world's electricity is from nuclear power, and in France it supplies three quarters of the country's electricity. About 440 power reactors are operational, total almost 400 GWe, and over 18,000 reactor years of experience have been accumulated. In 2018 they supplied 2563 TWh in 30 countries. About 55 more reactors are under construction, equivalent to about 15% of existing capacity, while an additional 110 are planned, equivalent to nearly one-third of existing capacity.

The significance of this role of nuclear energy is that it provides a reliable source of dispatchable power to meet base-load demand, continuous 24/7, with some scope for varying output for load-following. It does so generally at competitive cost and with no carbon dioxide emissions from the plants. It is extremely safe and its wastes are of relatively small volume and easily managed (Greeneche, 2021). The cost of waste management and decommissioning is normally internalized.

In its 60-year history nuclear power has mostly competed with coal and gas-fired generation, both of which are also dispatchable to meet demand, and hence the focus has been on cost, availability of fuel, and wastes—most recently CO₂—for each. This century the comparison has been increasingly with wind and solar power, and the contrast has been scale and reliability, with wind and grid-scale solar photovoltaic (PV) having significant system costs in addition to generation costs to consider. These escalate dramatically with increased share of intermittent renewables in the grid supply.² In addition, the proliferation of wind turbines across landscapes is in marked contrast to the limited space and profile of nuclear power plants.

Electricity has many uses in homes, commerce and industry. In addition there is both immediate and long-term potential for nuclear energy to provide a major contribution to world transport needs through expansion of its present role. Most obviously, there is the current provision of nuclear electricity to run major railway networks and the future expansion of this as electrification is extended. Here it replaces fossil fuels as a source of the electricity, making those networks a genuinely clean form of transport.

Nuclear power is immediately relevant to road transport and motor vehicles by replacing fossil fuels as a source of the electricity used for charging electric vehicles. This would ensure that these vehicles are properly zero-emission transport from the source of the electricity through to the actual on-road mobility. Plug-in hybrid and pure electric vehicles use electricity, and especially off-peak base-load power from the grid, for recharging. Their increased use is changing the pattern of daily demand, and this will become a major factor in electricity supply as car manufacturers increase the electric vehicle proportion of their output.

In addition, nuclear heat can be used for production of liquid hydrocarbon fuels from coal (see **Process heat** below) and also for biofuels. Further out, hydrogen for oil refining and for future fuel cell vehicles may be made electrolytically and, eventually, thermochemically using high-temperature reactors.

Widespread use of plug-in electric vehicles (PHEVs) and full-electric vehicles (EVs)—which get much of their energy from the electricity grid overnight at off-peak rates—will increase electricity demand by up to about 15% in developed countries. But more significantly it will mean that a greater proportion of the electricity can be generated by large-scale plant running continuously, and hence at low cost. This is likely to cause a 30–40% increased requirement for capacity to meet base-load demand, and a corresponding decrease in intermediate- and peak-load plant. This has the potential to lower all electricity costs significantly (large-scale continuous power supply being lower-cost per kWh), and where those base-load plants are nuclear, the power will also be emissions-free.

Industrial heat

Nuclear energy can produce heat for a variety of industrial applications, most obviously desalination to augment surface or artesian potable water supplies. Industrial process heat, particularly at high temperatures using gas-cooled reactors is a further application. Nautical propulsion, especially naval, is well established.

Desalination

World Energy Outlook 2016 (IEA, 2016) reported that in 2015, there were about 19,000 desalination plants worldwide, to provide water to both municipal and industrial users. Total world capacity in 2016 was 88.6 million m³/day (32,300 GL/year) of potable water. Almost half of global installed desalination capacity was in the Middle East, followed by the European Union with 13%, the USA with 9%, and North Africa with 8%. Globally, seawater is the most common feed water type, supplying about 60% of installed capacity, followed by brackish water at over 20%.

Desalination is very energy-intensive. The energy consumption for desalination is considerable: in 2016 the UAE used 556 TJ/year, followed by Saudi Arabia 168 TJ/year, Qatar 118 TJ/year and Kuwait 76 TJ/year, virtually all from fossil fuels.

²System costs are those costs between generation costs and providing a steady reliable supply to meet demand. They escalate dramatically as the proportion of intermittent wind and solar input to a system increases. *The Costs of Decarbonisation: System costs with high shares of nuclear and renewables* (NEA, 2019).

Reverse osmosis (RO) needs up to 6 kWh of electricity per cubic meter of seawater, hence 1 MWe will produce about 160 m³/h. For brackish water and reclamation of municipal wastewater, RO requires only about 1 kWh/m³. The choice of process generally depends on the relative economic values of fresh water and particular fuels, and whether cogeneration is a possibility. A variety of low-temperature heat sources may be used for thermal processes, including solar energy.

Small and medium sized nuclear reactors are suitable for desalination, often with cogeneration of electricity using low-pressure steam from the turbine and hot seawater feed from the final cooling system. The main opportunities for nuclear plants have been identified as the 80–100,000 m³/day and 200–500,000 m³/day ranges. US Navy nuclear powered aircraft carriers reportedly desalinate 1500 m³/day each for use onboard. Desalination can provide a way to vary substantially the amount of electricity supplied to the grid by a plant operating continuously at full power, in response to varying grid demand. Water is easily stored on any scale.

The feasibility of integrated nuclear desalination plants has been proven with over 150 reactor-years of experience, chiefly in Kazakhstan, India and Japan. Large-scale deployment of nuclear desalination on a commercial basis will depend primarily on economic factors. Egypt's planned El Dabaa nuclear power plant will use about 12% of its power for desalination, each reactor taking 432 MWt from the secondary circuit to produce 170,000 m³/day at a cost of less than \$1/m³.

Process heat

Apart from desalination, nuclear energy is an excellent source of process heat which can potentially be applied for various industrial applications including synthetic and unconventional oil production, oil refining, biomass-based ethanol production, and in the future: hydrogen production.

Coal can be used to make synthetic oil. The Fischer-Tropsch process was originally developed in Germany in the 1920s, and provided much of the fuel for Germany during the Second World War. It then became the basis for oil production in South Africa by Sasol, which now supplies about 30% of that country's gasoline and diesel fuel. The process consumes a significant quantity of hydrogen, using carbon monoxide in a catalytic reaction. The hydrogen is now produced with the carbon monoxide by coal gasification. The carbon monoxide then undergoes the water shift reaction to produce more hydrogen. A nuclear source of hydrogen coupled with nuclear process heat would triple the amount of liquid hydrocarbons from the coal and eliminate most CO₂ emissions from the process. There is considerable potential to extend world oil supplies, with negligible carbon footprint in their production, by this means.

The potential application of nuclear heat depends mainly on the temperature required. High temperature heat transfer from reactor to process can be by helium, salt or liquid metals. With future reactor output temperatures of up to 700 °C there is a wide range of possible applications, at 900 °C there are further possibilities, and at 950 °C an important application to hydrogen production opens up. About 20% of US energy consumption goes into process heat applications, compared with 35–40% into electricity. In this 20%, replacing fossil fuels with nuclear heat promises much in energy security, price stability and reduced regulatory risks, and it is the only option if carbon dioxide emissions are avoided.

In the European Union, the Nuclear Cogeneration Industrial Initiative (NC2I) (<http://www.snetp.eu/nc2i/>), part of the Sustainable Nuclear Energy Technology Platform (SNETP) is focused on high-temperature gas-cooled reactors (HTRs) producing 550 °C steam potentially for a variety of industrial applications.

The nuclear—hydrogen connection

Hydrogen is already a significant chemical product, about half of annual production being used in making nitrogen fertilizers via the Haber process and about half to convert low-grade crude oils (including those from tar sands) into transport fuels. Both uses of pure hydrogen are increasing significantly. Some is used for other chemical processes. World demand is about 70 million tonnes of pure hydrogen plus 45 million tonnes mixed with other gases and used in industry such as steel and methanol production, both kinds of demand growing steadily (IEA, 2019).

About 76% of pure hydrogen is made from natural gas and 23% from coal. This gives rise to 830 million tonnes of carbon dioxide emissions annually—each tonne produced gives rise to at least 11 tonnes of carbon dioxide. Electrolysis accounts for only 2%.

Hydrogen for transport

Like electricity, hydrogen is an energy carrier (but not a primary energy source). As oil becomes more expensive, hydrogen may replace it as a transport fuel and in other applications. This development becomes more likely as fuel cells are developed, with hydrogen as the preferred fuel. If natural gas also becomes expensive, or constraints are put on carbon dioxide emissions, non-fossil sources of hydrogen will become necessary.

As with electricity, hydrogen for transport use will tend to be produced near where it is to be used. This will have major geopolitical implications as industrialized countries become less dependent on oil and gas from distant parts of the world.

Hydrogen can be produced economically by electrolysis of water in off-peak periods, enabling much greater utilization of base-load plants, and in particular nuclear plants. In future, the heat from high-temperature reactors could be used directly for thermochemical production of hydrogen.

All this points to the fact that while a growing hydrogen economy already exists, linked to the worldwide chemical and refining industry, a much greater one is possible (IEA, 2019). With new uses for hydrogen as a fuel, the primary energy demand for its production may approach that for electricity production. Nuclear power already produces electricity as a major energy carrier. It is well placed to produce hydrogen if this becomes a major energy carrier also.

An electricity system based on nuclear power could produce hydrogen at a steady rate or simply off-peak and store it underground so that it was used in large banks of fuel cells (e.g. 1000 MWe) at peak demand periods each day. Efficiency would be enhanced if by-product oxygen instead of air were used in the fuel cells.

In motor vehicles, hydrogen can be burned in a normal internal combustion engine, and some test cars are thus equipped. However, its main use is likely to be in fuel cells. A fuel cell is conceptually a refuelable battery, making electricity as a direct product of a chemical reaction. But where normal batteries have all the active ingredients built in at the factory, fuel cells are supplied with fuel from an external source. Fuel cells catalyze the oxidation of hydrogen directly to water at relatively low temperatures while producing electricity.

Hydrogen can also be used for stand-alone small-scale stationary generating plants using fuel cells—where higher temperature operation (e.g. of solid oxide fuel cells) and hydrogen storage may be less of a problem, or where hydrogen is reticulated like natural gas.

Considering the storage and portability challenges of hydrogen itself, as well as the radical change to fuel cell cars, attention has turned to methanol (CH_3OH), which can be made from CO_2 and hydrogen, and used in conventional internal combustion engines. It has about half the energy density of petrol/gasoline. For diesel engines, dimethyl ether (DME, $\text{CH}_3\text{—O—CH}_3$) is better than methanol, and DME is made by dehydrating methanol molecules. World production capacity of DME is over 10 million tonnes per year.

Hydrogen for agricultural fertilizers

According to Norman Borlaug, 1970 Nobel laureate and “grandfather of the green revolution,” organic nitrogen compounds present in the world’s soils are only sufficient to feed one-third of today’s population. The rest must come from inorganic additions. Most of the world’s nitrogen fertilizers are made using the Haber³ process, combining abundant atmospheric nitrogen with hydrogen. The resulting ammonia is then oxidized to nitrates. But the hydrogen has to be made from fossil fuels, principally methane, i.e. natural gas. This is costly and it gives rise to substantial carbon dioxide emissions.

If nuclear energy is used to make the hydrogen from water, the carbon dioxide is avoided and a valuable organic chemistry feedstock is conserved. An abundant supply of low-cost hydrogen would greatly boost world agricultural productivity through increased availability of nitrogen fertilizers.

Hydrogen for oil refining

A major use of hydrogen today is hydrogenation of heavy crude oil, a process that breaks down the long-chain hydrocarbons to yield synthetic crude oil (about 5 kg of hydrogen is used per barrel). Steam reforming of natural gas is used to produce the hydrogen feedstock. Nuclear power could make this steam and electricity, and use some of the electricity in high-temperature electrolysis for hydrogen production.

Nuclear propulsion

Marine propulsion

Work on nuclear marine propulsion started in the 1940s, and the first test reactor started up in the United States in 1953. The first nuclear-powered submarine, *USS Nautilus*, put to sea in 1955. This led to the development of reactors and propulsion systems mostly for naval vessels in several countries. Today over 140 vessels are powered by about 180 small nuclear reactors and more than 12,000 reactor-years of marine operation has been accumulated.

Nuclear propulsion has proven technically and economically essential in the Russian Arctic where operating conditions are beyond the capability of conventional icebreakers. The power levels required for breaking ice up to 3 m thick, coupled with refueling difficulties for other types of vessels, are significant factors. Russia’s nuclear fleet, with six nuclear icebreakers and a nuclear freighter, has increased Arctic navigation from 2 to 10 months per year, and in the Western Arctic, to year-round.

The Russian LK-60 icebreakers now being commissioned are “universal” dual-draught (10.5 m with full ballast tanks, minimum 8.55 m), displacing up to 33,540 t (25,450 t without ballast), for use in the Western Arctic year-round and in the eastern Arctic in summer and autumn. They are 173 m long, 34 m wide, and designed to break through 2.8 m thick ice at up to 2 knots. The wide 33 m beam at waterline is to match the 70,000 t ships they are designed to clear a path for, though a few ships with reinforced hulls

³German scientist Fritz Haber invented the process in 1909 and received the Nobel Prize for chemistry in 1918 for creating “an exceedingly important means of improving the standards of agriculture and the well-being of mankind,” which seems a considerable understatement. $\text{N}_2 + 3\text{H}_2 \rightarrow 2\text{NH}_3$ (at 15–25 MPa and 400–500°C). The Haber process produces about 500 million tonnes of nitrogen fertilizer per year and consumes about half of the hydrogen produced annually.

are already using the Northern Sea Route. The LK-60 is powered by two RITM-200 reactors of 175 MWt each which together deliver 60 MW at the three propellers via twin turbine-generators and three electric motors.

In 1988, the *NS Sevmorput* was commissioned in Russia, mainly to serve northern Siberian ports but more recently as a freighter for fresh food from east coast across the north of Siberia to the west. It is a 61,900 t LASH carrier (taking lighters to ports with shallow water) and container ship with ice-breaking bow. It is powered by a similar KLT-40 reactor to that used in the ice-breakers, delivering 32.5 propeller MW from the 135 MWt reactor, and it needs refuelling only every 15 years.

Nuclear power gives submarines and large naval ships unmatched performance. The Russian, US and British navies as well as Russian icebreakers until the latest models rely on steam turbine propulsion, the French and Chinese in submarines use the turbine to generate electricity for propulsion. All power plants are pressurized water reactors (PWR), except the ill-fated Russian *Alfa* class.

With increasing attention being given to greenhouse gas emissions arising from burning fossil fuels for international air and marine transport, particularly dirty bunker fuel for the latter, and the excellent safety record of nuclear-powered ships, it is likely that there will be renewed interest in marine nuclear propulsion. Large bulk carriers that go back and forth constantly on few routes between dedicated ports could be powered by a reactor delivering 100 MW thrust. The world's merchant shipping is reported to have a total power capacity of 410 GWt, about one third that of world nuclear power plants. So far, exaggerated fears about safety have caused political restriction on port access.

Space propulsion

Nuclear fission reactors for space programs have mainly been Russian. But for higher power requirements than RTGs can provide, fission power systems (FPS) have a distinct cost advantage over Radioisotope Thermoelectric Generators (RTGs). As currently conceived, FPS would be launched cold, with essentially no radioactive hazards. Reactor start-up is after the device is in orbit. Then the reactor automatically responds to thermal load changes and maintains safe operating temperatures based on negative temperature reactivity feedback, giving it load-following capability.

Between 1967 and 1988 the former Soviet Union launched 31 low-powered fission reactors in Radar Ocean Reconnaissance Satellites (RORSATs) on Cosmos missions. They utilized thermoelectric converters to produce electricity. Russia is now working on reactors in the megawatt power range, for long-haul interplanetary missions.

In USA, the National Aeronautics and Space Administration (NASA) and the Department of Energy (DOE) are developing fission power technology to serve a wide range of future space uses. More-conventional fission power systems employing liquid-metal-cooled pin-fuel reactors and dynamic power conversion are well suited for lunar and Mars surface power or nuclear electric propulsion (NEP) applications.

Heatpipe Power System (HPS) reactors are compact fast reactors producing up to 100 kWe for about 10 years to power a spacecraft or planetary surface vehicle. They have been developed since 1994 at the Los Alamos National Laboratory as a robust and low technical risk system with an emphasis on high reliability and safety. NASA is currently focused on its KiloPower space reactors. They may include a variety of designs of comparable power and mass to RTGs. They use liquid metal heat pipes to transfer fission heat to either thermoelectric or Stirling power conversion. Beyond that it plans MegaPower reactors producing 2 MWe.

Neutron applications and treatments

Research reactors, much smaller than power reactors designed to produce and exploit heat, are well established around the world to supply neutrons for research, to treat or test materials for specialist applications, and to produce radioisotopes for medicine and industry. Research reactors are essentially neutron factories, and about 220 operate in 53 countries (86 in developing countries). Their neutron beam output can have different characteristic depending on designed use. Test reactors are more powerful than most.

Some research reactors operate with high-enriched uranium fuel and international efforts have substituted low-enriched fuel (below 20% U-235) in most of these. Some radioisotope production also uses high-enriched uranium as target material for neutrons and this is being phased out in favor of low-enriched uranium. Research reactors are simpler than power reactors, and operate at lower temperatures. They need far less fuel, and far less fission products build up as the fuel is used.

Many research reactors are used with international collaboration, and the products of those used for isotope production are certainly traded internationally. The IAEA has designated two international research hubs based on research reactors, giving them ICERR⁴ status valid for 5 years. The first is in France, based on CEA's Saclay and Cadarache facilities, the second is in Russia, the Research Institute of Atomic Reactors (RIAR) at Dimitrovgrad, with six research reactors available to IAEA member states.

Neutron beams are uniquely suited to studying the structure and dynamics of materials at the atomic level. Neutron scattering is used to examine samples under different conditions such as variations in vacuum pressure, high temperature, low temperature and magnetic field, essentially under real-world conditions.

A fuller treatment of the wide range of radiation applications is in the chapter by Bezdek (2021) in this encyclopedia. He makes it clear that modern society cannot function without nuclear technologies and that the benefits of these technologies are enormous and widespread.

Neutron activation

This process is used to produce the radioisotopes, widely used in industry and medicine. It involves bombarding particular elements with neutrons which are captured by atomic nuclei so that each target nucleus has a neutron added and becomes radioactive, or possibly fissions.

For instance, cobalt-59 can capture a neutron to become cobalt-60, a widely-used source of gamma radiation as it decays to nickel-60. But if lithium-7 captures a neutron it fissions into helium and tritium. The most widely used isotope in nuclear medicine is technetium-99 m, a decay product of molybdenum-99. This is usually produced by irradiating a target of uranium foil with neutrons (for a week or so) and then separating the molybdenum-99 from the other fission products of U-235 in a hot cell—the Mo-99 being about 6% of the fission products.

Neutron activation analysis is a sensitive and accurate means of trace element analysis, where emissions from the radioactive product can be measured, regardless of its chemical form.

Neutron transmutation doping

NTD changes the properties of silicon, making it highly conductive of electricity. Large, single crystals of silicon shaped into ingots, are irradiated inside a reactor reflector vessel. Here the neutrons change one atom of silicon in every billion to phosphorus. The irradiated silicon is sliced into chips and used for a wide variety of advanced computer applications. NTD increases the efficiency of the silicon in conducting electricity, an essential characteristic for the electronics industry.

Materials testing

In materials testing reactors, materials are also subject to intense neutron irradiation to study changes. For instance, some steels become brittle under such conditions, and alloys which resist embrittlement must be used in nuclear reactors.

Radioisotopes

The attributes of naturally decaying atoms, known as radioisotopes, give rise to their multiple applications across many aspects of life. There are about 50 million nuclear medicine procedures each year, saving many lives.

There are hundreds of natural radioisotopes representing stages in the decay of those which were formed primordially. But most of those used in the applications described below are made in research reactors, and are relatively short-lived. Their decay sequence is according to their physical characteristics, just the same as for those occurring naturally.

Nuclear medicine

The use of radiation and radioisotopes in medicine, particularly for diagnosis (identification) and therapy (treatment) of various medical conditions is widespread and well established. In developed countries (a quarter of the world population) about one person in 50 uses diagnostic nuclear medicine each year, and the frequency of therapy with radioisotopes is about one-tenth of this.

Nuclear medicine uses radiation to provide information about the functioning of a person's specific organs or to treat disease. In most cases, the information is used by physicians to make a quick, accurate diagnosis of the patient's illness. The thyroid, bones, heart, liver and many other organs can be easily imaged, and disorders in their function revealed. In some cases radiation can be used to treat diseased organs, or tumors. Five Nobel Laureates have been intimately involved with the use of radioactive tracers in medicine.

Over 10,000 hospitals worldwide use radioisotopes in medicine, and about 90% of the procedures are for diagnosis. The most common radioisotope used in diagnosis is technetium-99 (Tc-99), with some 40 million procedures per year, accounting for about 80% of all nuclear medicine procedures worldwide. In the United States there are over 20 million nuclear medicine procedures per year among 310 million people, and in Europe about 10 million among 500 million people.

Nuclear medicine was developed in the 1950s by physicians with an endocrine emphasis, initially using iodine-131 to diagnose and then treat thyroid disease. In recent years specialists have also come from radiology, as dual computerized tomography with positron emission tomography (CT/PET) procedures have become established, increasing the role of accelerators in radioisotope production. However, the main radioisotopes such as technetium cannot effectively be produced in useful quantities and purity without reactors.

Sterilization is an important medical-related use of radioisotopes having strong gamma emission, such as cobalt-60, or X-rays or electron beams. Many medical supplies are sterilized without heat, and after being packaged. More than 160 gamma irradiation plants worldwide are used to sterilize medical equipment and supplies. The coronavirus pandemic has highlighted the importance of sterile personal protective equipment, though face masks are an exception due to damage from the high levels of radiation involved.

Radioisotopes in industry

Radioisotopes are used by manufacturers as tracers to monitor fluid flow and filtration, detect leaks, and gauge engine wear and corrosion of process equipment. Small concentrations of short-lived isotopes can be detected while no residues remain in the environment. By adding small amounts of radioactive substances to materials used in various processes it is possible to study the mixing and flow rates of a wide range of materials, including liquids, powders and gases and to locate leaks. Radiotracers are used widely in industry to investigate processes and highlight the causes of inefficiency. They are particularly useful where process optimization can bring material benefits, such as in the transport of sediments. Radiotracers are also used in the oil and gas industry to help determine the extent of oil fields.

Radioactive materials are used to inspect metal parts and the integrity of welds across a range of industries. Industrial gamma radiography utilizes the ability of various types of radiation to penetrate materials to different extents. Gamma radiography works in much the same way as X-rays screen luggage at airports. Instead of the bulky machine needed to produce X-rays, all that is needed to produce effective gamma rays is a small pellet of radioactive material in a sealed titanium capsule. The capsule is placed on one side of the object being screened, and some photographic film is placed on the other side. The gamma rays, like X-rays, pass through the object and create an image on the film. Just as X-rays show a break in a bone, gamma rays show flaws in metal castings or welded joints. The technique allows critical components to be inspected for internal defects without damage.

The process of gamma radiography, a type of non-destructive testing, is used to validate the integrity of poured concrete and welds on fluid vessels, pipelines or critical structural elements. The unique characteristics of gamma radiography have resulted in the technique becoming a crucial tool throughout multiple industries.

Gauges containing radioactive (usually gamma) sources are in wide use in all industries where levels of gases, liquids and solids must be checked. The IAEA estimates that several hundred thousand such gauges are operating in industry worldwide. They measure the amount of radiation from a source which has been absorbed in materials. These gauges are most useful where heat, pressure or corrosive substances, such as molten glass or molten metal, make it impossible or difficult to use direct contact gauges.

Radioisotopes in environmental management and water resources

Radioactive tracers (or radiotracers) play an important role in detecting and analyzing pollutants since even very small amounts of a given radioisotope can easily be detected, and the decay of short-lived isotopes means that no radioactive residues remain in the environment. Hydrologists use radiotracers to determine the passage and pace of pollutants moving through groundwater to assess the level of vulnerability.

Radioisotope hydrology techniques enable accurate tracing and measurement of the extent of underground water resources. Such techniques provide important analytical tools in the management and conservation of existing supplies of water and in the identification of new, renewable sources. They provide answers to questions about origin, age and distribution of groundwater, as well as the interconnections between ground and surface water and aquifer recharge systems. The results permit planning and sustainable management of these water resources. For surface waters they can give information about leakages through dams and irrigation channels, the dynamics of lakes and reservoirs, flow rates, river discharges and sedimentation rates. There are some 60 countries, developed and developing, that have used isotope techniques to investigate their water resources in collaboration with IAEA. The isotopes measured may be naturally-occurring or added.

An allied technology, neutron probes, can measure soil moisture very accurately, enabling better management of land affected by salinity, particularly in respect to irrigation. A neutron probe suspended on a cable is lowered down a hole. A typical one contains a pellet of americium-241 and beryllium. The alpha particles emitted by the decay of the americium produce neutrons when they collide with the light beryllium nuclei. The probe also contains a measuring device which detects what happens to the neutrons after they encounter hydrogen nuclei and gives an indication of soil moisture.

Radioisotopes in the home

The main application of radioisotopes in the home is in smoke detectors. A common type is ionization smoke detector which contains a small amount of americium-241 as an oxide. Americium-241 emits alpha particles and low energy gamma rays. The alpha particles emitted by the Am-241 collide with the oxygen and nitrogen in air within the detector's ionization chamber to produce charged particles (ions). A low-level electric voltage applied across the chamber is used to collect these ions, causing a steady, small electric current to flow between two electrodes. When smoke enters the space between the electrodes, the smoke particles attach to the charged ions, neutralizing them. This causes the number of ions present—and therefore the electric current—to fall, which sets off an alarm.

Tritium and promethium-147 release beta particles during decay, triggering a chemical reaction upon contact with other materials, which creates a "glow" as perceived by the human eye. These properties—known as radioluminescence—make the isotopes useful for providing "light" in the absence of electricity. These materials are used in clocks, watches and gun sights so that they can be used at night, as well as in "exit" signs in commercial buildings and aircraft/ships. Earlier watches and the dials of other instruments utilized radium for the same purpose.

Radioisotopes in space

Radioisotope power sources have been an important source of energy in space since 1961. Radioisotope Thermoelectric Generators (RTGs) have been the main electricity source for space work.

The high decay heat of plutonium-238 (0.56 W/g) enables its use as an electricity source in the RTGs of spacecraft, satellites and navigation beacons. Its intense alpha decay process with negligible gamma radiation calls for minimal shielding. Americium-241, with 0.15 W/g, is another source of energy, favored by the European Space Agency, though it has some relatively low-energy gamma radiation.

In an RTG, heat from the oxide fuel is converted to electricity through static thermoelectric elements (solid-state thermocouples), with no moving parts. RTGs are safe, reliable and maintenance-free and can provide heat or electricity for decades under very harsh conditions, particularly where solar power is not feasible. So far over 45 RTGs have powered over 25 US space vehicles including Apollo, Pioneer, Viking, Voyager, Galileo, Cassini, Ulysses and New Horizons space missions as well as many civil and military satellites. RTGs range up to nearly 1 kW.

As well as RTGs, Radioactive Heater Units (RHUs) are used on satellites and spacecraft to keep instruments warm enough to function efficiently. Their output is only about 1 W and they mostly use Pu-238.

Summary

The enormous range of uses for nuclear energy itself, the neutrons it produces, and their derivative products in hundreds of different radioisotopes means that the suite of nuclear technologies is a vital, if inconspicuous, part of today's world. Modern science, medicine and industry could not function without them. Bezdek (2021) estimates that international markets for these technologies exceed US\$500 billion annually and are growing rapidly.

Glossary

Cross-section Probability of neutron interaction with a nucleus, expressed in terms of area, in units of barns (b). One barn equals $1.0 \times 10^{-24} \text{ cm}^2$.

Enrichment Tails (also Depleted Uranium) The uranium remaining after the enrichment of natural uranium into fuel, today about 0.3% ^{235}U , earlier 0.2–0.25% ^{235}U .

Enrichment The fraction of an isotope, usually fissile ^{235}U , in a mass of uranium. Enrichment is commonly quoted as the weight percent of the particular isotope. Natural uranium has an enrichment of 0.711 wt%, commercial reactor fuel is 3–5% enriched and depleted uranium is 0.2–0.3 wt% ^{235}U .

Fractionation Crystallization from a magma in which the initial crystals are prevented from equilibrating from the parent liquid, resulting in a series of residual liquids of more extreme composition than would have resulted from continuous reaction.

Gangue Material that has no commercial value surrounding or mixed with the commercially valuable material in an ore deposit.

Geoneutrino An electron anti-neutrino emitted within the earth in the β -decay of ^{232}Th , ^{238}U or ^{40}K and their decay product nuclei.

High Activity Low Enriched Uranium (HALEU) Uranium containing between 5 wt% and 20 wt% ^{235}U .

Highly Enriched Uranium (HEU) Uranium containing more than 20 wt% ^{235}U .

J_{th} Joule (i.e. Watt-second) thermal. One British Thermal Unit (BTU) equals $1055 J_{\text{th}}$.

Log-Normal Distribution A distribution of the form $f(x) = e^{-(\ln x)^2}$. In the present usage the tonnage of an element available at concentration c , $T(c)$, is given by $T(c) = C_1 e^{-(\ln c_0 - \ln c)^2}$, where c_0 is the average crustal abundance and C_1 is a constant.

Low Enriched Uranium (LEU) Uranium containing less than 5 wt% ^{235}U .

Mafic Composed chiefly of dark ferromagnesian minerals.

MOX Mixed OXide fuel, usually consisting of a ceramic mixture of uranium dioxide and plutonium dioxide.

MSWU Mega-Separative Work Unit, a million separative work units. A Separative Work Unit is the separative work that must be done to one kilogram of a mixture of isotopes to change its separation potential by one unit. The separation potential, a dimensionless function, is defined by $\phi x_k = 2x_k - 1 \ln \frac{x_k}{1-x_k}$, where x_k is the atomic fraction of the isotope, k . See [Benedict \(1981, p. 667\)](#) for a more complete definition.

Nebula Clouds of gas and (and later dust particles) surrounding the site of a core-collapse supernova explosion. Depending on the density and energy of the nebula, the clouds gradually accrete into new stars and planetary systems.

Pegmatite An exceptionally coarse-grained igneous rock, with interlocking crystals, often found at the margins of batholiths

Placer A mineral deposit at the surface formed by sedimentary concentration of heavy mineral particles from weathered debris.

Quad Quadrillion (i.e. 1×10^{15} , also written 1E15) British Thermal Units. One quad = $1.055 \times 10^{18} J_{\text{th}}$.

t Metric ton, also used in Mt, million metric tons, and Tt, trillion metric tons (teratons).

Unconformity A break or gap in the geologic record, such as an interruption in the normal sequence of deposition of sedimentary rocks, or a break between eroded metamorphic rocks and younger sedimentary strata ([Bates and Jackson, 1984](#)).

wppb Weight parts per billion, also: wppm weight parts per million and wppt weight parts per trillion.

Yellowcake A concentrate of uranium ore, containing 80–90% U_3O_8 . Yellowcake ranges from yellow to black, depending on impurities, processing temperature and degree of hydration (NRC, 2020). Although uranium prices are sometimes colloquially cited as “dollars per pound of yellowcake,” the actual prices are \$ per lb of U_3O_8 , where all of the uranium is assumed to be present in the yellowcake as that oxide.

Introduction

Beginning with the discovery of nuclear fission in 1938, uranium has been seen as a valuable but scarce resource. Natural uranium is predominately ^{238}U (99.27 atom %) and only about 0.72 atom % is ^{235}U , the only naturally occurring isotope that can be made to fission with thermal neutrons. Consequently, the resources of uranium have been believed to inherently limit the sustainability of nuclear energy. Both ^{238}U and thorium (entirely ^{232}Th) are fertile, meaning that they can be converted to the fissile isotopes ^{239}Pu and ^{233}U respectively, through neutron irradiation. Therefore a consideration of nuclear fuel resources for the coming centuries must include both uranium and thorium.

Origins of fissile materials

Before discussing the resources and distribution of uranium and thorium on earth, it is important to first have a cursory understanding of the original sources of these elements, and all elements heavier than iron. This process of nucleosynthesis occurs in core collapse supernovae and in neutron star mergers. A supernova occurs when a massive star, generally more than ten solar masses, has consumed so much of the hydrogen and helium in its core that it can no longer support the gravitational pressure of outer layers of gas. The core temperature and pressures reach a point where the nuclei dissociate and the overlying layers collapse into the center. The dissociated neutrons collide with nuclei in the infalling layers and form heavier nuclei, including uranium and thorium. A binary neutron star merger occurs when two neutron stars spiral together to form a larger neutron star or a black hole. Neutron star mergers are now being detected by the Laser Interferometer Gravitational-Wave Observatory (LIGO) facilities in Washington state and Louisiana and a similar observatory, Virgo, near Pisa, Italy (Abbott et al., 2017). Gravitational wave signals from the neutron star merger GW170817 in 2017, indicated that during the 100 seconds before the merger, the two neutron stars increased their spiraling frequency from 24 revolutions per second to several hundred revolutions per second. The total mass of the pair was 2.8 solar masses.

The energy available to stars is governed, to first order, by the Curve of Binding Energy, shown in Fig. 1. Binding energy, as the name implies, is the energy required to separate a proton or neutron from a nucleus. Generally, binding energy is expressed as MeV per nucleon. Larger binding energies indicate that a particular nucleus is more tightly bound together. Thus the light nuclei, such as

Fig. 1 Curve of binding energy.

^2H (“deuterium”), ^3H (“tritium”) and ^3He have small binding energies, while ^4He has a much higher binding energy. The reactions where two nuclei collide and form a larger nucleus, fusion reactions, such as $^2\text{H} + ^2\text{H} \rightarrow ^3\text{H} + \text{p}$ or $^2\text{H} + ^3\text{H} \rightarrow ^4\text{He} + \text{n}$, release energy because their product nuclei are more tightly bound. The energy is primarily kinetic energy of the resulting nuclei. Thus a fusion reaction between two nuclei heavier than ^{56}Fe requires the input of energy, usually as kinetic energy of the two colliding nuclei. If a ^{235}U nucleus is struck by a neutron and fissions into two fission fragments containing 90–140 nucleons, the reaction releases about 0.85 MeV/nucleon or about 200 MeV for the total reaction, again mainly as kinetic energy of the fission fragments.

Stars derive their energy through the fusion of hydrogen into helium and then further fusion reactions combine nuclei into carbon and all of the elements up to iron. As this process proceeds over millions of years the hydrogen and helium are consumed, especially at the center of the stars. The fusion reactions among nuclei from carbon up to iron yield less and less energy, while the outer layers of the stars continue exerting tremendous gravitational pressures on the core. A star the size of our sun is burning slowly and will expand as a red giant, engulfing the earth and collapse into a white dwarf in about 7 billion years. Our sun can produce the elements up to iron but doesn’t have the mass to drive the endothermic reactions producing substantial amounts of the elements heavier than iron.

Thus the question puzzling most astrophysicists in the mid-20th century was: Why is there tungsten or molybdenum or rhenium or uranium or any of the other elements heavier than iron in the earth?

Newly-built particle accelerators and accumulating data combined with the understanding of transient processes coalesced in a paper by Burbidge, Burbidge, Fowler and Hoyle, known as B²FH (Margaret Burbidge et al., 1957). (Margaret Burbidge, the first author, died on April 5, 2020 at the age of 100. She was an inspiration to generations of astrophysicists.) That paper explains the difference between the slow process (“s-process”) and a rapid one (“r-process”). In our sun the s-process is dominant and progressively heavier isotopes accumulate on a time scale long compared with the radioactive decay of the resulting nuclei (e.g. 10–100 years). Thus nuclei decay without absorbing additional neutrons. The r-process occurs in cataclysmic supernovae and neutron star mergers, where the average nucleus undergoes about 100 neutron collisions per second, much faster than the decay rate.

The first cataclysmic event suggested for the r-process was a supernova in which the depletion of light nuclei at the center of large stars (> 10 solar masses) reduces energy production in the core and there is a sudden collapse of the outer layers into the core. The compression of the core causes a degenerate state within the core in which the nuclei separate into the constituent protons and neutrons over the course of a few minutes. The resulting flash of neutrons and neutrinos meet the infalling outer layers, flowing at a rate of about one solar mass per second, and are sufficient to stop that inflow and to blow off the outer layers of the star. The collisions between the infalling heavy nuclei and outflowing neutrons produce heavier nuclei up to and beyond uranium with neutron fractions out to the “neutron drip edge.”

Wanajo et al. (2003) modeled the distribution of isotopes during 2.5 s of nucleosynthesis following the flash of neutrons and neutrinos in a supernova. Three charts of the nuclides at 0.48, 0.58 and 2.13 s after the neutrino flash are shown in Fig. 2

At $t = 0.48$ s in Fig. 2, nuclei are repeatedly absorbing neutrons as they progress up the chart near the neutron “drip edge,” where no more neutrons can be absorbed. By $t = 0.58$ s, short-lived beta decays have taken place to move the abundances up and to the left. Notice that higher abundances appear with values of N just below the quantum “magic numbers” of 50, 82 and 126.

Our understanding of the astrophysical nucleosynthetic processes occurring during the collapse of a supernova has progressed in the last 25 years both through spectroscopic observations of the interstellar dust that is eventually accreted into planets and through simulations of the nuclear processes during the collapse. Since these supernovae and neutron star mergers are the source of all elements heavier than iron, these observations and simulations can provide estimates of the constituents that formed the earth.

Core-collapse supernova implosions are estimated to occur, somewhere in the universe, at the rate of one per second. Obviously, most such implosions are too distant or masked by dust clouds and are not detected from the earth. Since the beginning of the universe, some interstellar material has gone through multiple cycles of collapse, explosion, dispersal, and accretion into new stars and planets.

The hydrodynamic instabilities of the implosion result in a wide variation in the shapes of the resulting nebulae. Nevertheless, neutron transport and reaction codes have been developed to estimate the distribution of isotopes resulting from nucleosynthetic events. Further simulations of planetary formation have produced models of the Bulk Silicate Earth based on the abundance of various elements and their chemical characteristics (McDonough and Sun, 1995). These BSE models assume that the earth has a uniform composition. As shown in Fig. 3, the uranium abundance in mass should be about seven orders of magnitude less than that of silicon. Since the chemical and planetary accretion characteristics of silicon, uranium and thorium are similar, and since the earth is about 10% silicon, one would expect that the overall concentration of uranium in the earth is about 10 weight parts per billion (wppb) and that thorium should be about 40 wppb.

Stated in other terms, the global inventory is approximately 60 Tt (60×10^{12} t) of uranium and approximately 240 Tt of thorium. Although this inventory is a vast amount of both elements, if uranium and thorium had a uniform distribution throughout the earth, as assumed in the cold accretion model, concentrations of uranium and thorium would be far too small to be economically extracted.

Geoneutrino estimates of uranium and thorium

In the last twenty years, however, a decay product of the 4.5 billion year-half-life of ^{238}U and the 14.2 billion year-half-life of ^{232}Th , has been used to estimate the total global inventory of uranium and thorium. These particles, called neutrinos, are extremely

Fig. 2 Isotopic distribution following a core-collapse supernova (Wanajo et al., 2003). Y is the abundance of each isotope normalized to the initial proton abundance. The color scale for the abundances range from $1\text{E-}10$ (dark red) to $1\text{E-}02$ (white) times the initial proton abundance. A is the mass number, Z is the proton number and N is the neutron number for the nuclei. The larger white dots indicate stable or long-lived isotopes. Note that ^{232}Th , ^{235}U and ^{238}U are the uppermost stable or long-lived isotopes. Short-lived neutron-poor isotopes are not shown.

Fig. 3 Composition of the bulk silicate Earth.

difficult to detect and most neutrinos pass completely through the earth without interacting. Thus neutrino detectors are usually a thousand tons in mass and must be located deep underground to avoid unwanted signals caused by cosmic rays.

Neutrinos occur in three types: electron, muon and tau. Each of the three types has a corresponding anti-neutrino. Neutrinos originating within the earth, termed *geoneutrinos*, are actually electron anti-neutrinos primarily resulting from the decay of ^{40}K , ^{238}U and ^{232}Th . Geoneutrinos provide a means for estimating the total uranium and thorium content of the earth and also may provide limited information on the location of those resources. These elementary particles have been measured over the past decade by massive detectors in Japan, Canada and Europe in an effort to differentiate the radiogenic and gravitational components of the total geothermal energy flux through the earth's surface (Davies and Davies, 2010; Ludhova and Zavatarelli, 2013). Neutrino and antineutrino fluxes have also been measured to understand neutrino oscillations, to investigate solar fusion processes and as a first signal of supernova events. Neutrinos (and anti-neutrinos) travel close to the speed of light, have a small mass (< 2 eV) and lack an electric charge. When an electron anti-neutrino collides with a proton, the result is a neutron and a positron (i.e. an anti-electron). This reaction, known as the neutron inverse β decay, was used in the first detection of the neutrino in the Cowan-Reines experiment of 1956. Following the neutron inverse β decay, the positron reacts with a nearby electron to produce two 511 keV gamma rays. The neutron is absorbed by a hydrogen nucleus, releasing a characteristic 2.2 MeV gamma with a mean delay of ~ 200 μs . Circuitry in the detector registers a neutrino event through the delayed emission of a 2.2 MeV gamma following two 511 keV gammas.

As shown in Table 1, the decay chain of ^{238}U into ^{206}Pb results in 6 anti-neutrinos, one anti-neutrino for each beta decay. Similarly, the decay of ^{232}Th in ^{208}Pb results in 4 anti-neutrinos. (Fiorentini et al., 2004). Because of the neutron inverse β decay requires an electron anti-neutrino threshold energy of 1.80 MeV, KamLAND cannot detect ^{40}K anti-neutrinos, but anti-neutrinos from both ^{238}U and ^{232}Th are within the range of this instrument.

The KamLAND (the Kamioka Large Anti-Neutrino Detector), in central Japan, consists of a 18 m diameter spherical vessel which in turn contains a 13 m diameter nylon balloon (Araki et al., 2005). The balloon contains approximately 1000 metric tons of a liquid scintillator (mineral oil, benzene and fluorescent compounds). The volume between the balloon and the spherical vessel contains highly purified oil which shields the balloon from external radiation and provides buoyancy to support the liquid scintillator. About 1900 photomultiplier tubes are mounted on the inner surface of the spherical vessel. Surrounding the spherical vessel is a water Cherenkov detector which provides additional shielding and acts as a muon veto counter.

Table 1 The main properties of geoneutrinos.

Decay	Q (MeV)	$\tau_{1/2}$ (10^9 year)	E_{max} (MeV)	ϵ_H (W/kg)	$\epsilon_{\bar{\nu}_e}$ ($\text{kg}^{-1} \text{s}^{-1}$)
$^{238}\text{U} \rightarrow ^{206}\text{Pb} + 8\ ^4\text{He} + 6\ e + 6\ \bar{\nu}_e$	51.7	4.47	3.26	0.95×10^{-4}	7.41×10^7
$^{232}\text{Th} \rightarrow ^{208}\text{Pb} + 6\ ^4\text{He} + 4\ e + 4\ \bar{\nu}_e$	42.7	14.0	2.25	0.27×10^{-4}	1.63×10^7
$^{40}\text{K} \rightarrow ^{40}\text{Ca} + e + \bar{\nu}_e$	1.32	1.28	1.31	0.36×10^{-8}	2.69×10^4

$\bar{\nu}_e$ denotes electron anti-neutrinos. Q is the energy release for the overall decay chain; $\tau_{1/2}$ is the half-life of the parent isotope; E_{max} is the maximum antineutrino energy in the decay chain; ϵ_H is the heating rate, per kg of the parent isotope; $\epsilon_{\bar{\nu}_e}$ is the electron antineutrino source rate, per kg of the parent isotope.

Table 2 U and Th masses in Reservoirs and in the Bulk Silicate Earth (BSE) model as described in the reference model based on geoneutrino signals from 16 locations (Huang et al., 2013).

	Thickness (km)	U mass (10^{15} kg)	Th mass (10^{15} kg)
Continental crust			
Sediment	1.5	1.2	5.8
Upper crust	11.6	18.2	70.7
Middle crust	11.4	6.6	33.3
Lower crust	10	1.0	6.0
Lithospheric mantle	140	2.9	14.5
Oceanic crust			
Sediment	0.6	0.6	2.8
Crust	7.4	0.4	1.3
Depleted mantle	2090	25.7	70.6
Enriched mantle	710	24.0	113.7
Bulk silicate earth	2891	80.7	318.8

Huang et al. (2013) developed a Reference model of the heat-producing elements in the reservoirs shown in Table 2. The overall results of the KamLAND and Borexino geoneutrino detectors were used to estimate the distribution of Heat Producing Elements (i.e. U, Th and K) in the various reservoirs and those trial distributions were used in a Monte Carlo study to predict the geoneutrino flux at 16 detectors worldwide. The total masses of U and Th in the reservoirs show good agreement with the Bulk Silicate Earth model and also agree with the predictions of (U+Th)/Si ratios from supernova and neutron star merger studies.

The geoneutrino signal and the reference model also indicate that the masses of uranium and thorium in the upper continental crust (UCC) are about 18×10^{15} kg and 70×10^{15} kg, respectively.

Concentration mechanisms for uranium in the Earth's crust

Unlike other energy resources such as coal or petroleum, the resources of uranium are not fundamentally changed by geological processes. Whereas petroleum might be lost through evaporation or combustion or a natural gas reservoir may vent into the atmosphere, uranium is lost only through radioactive decay or through the relatively rare formation of a natural reactor. Therefore the primordial inventory of uranium, reduced by radioactive decay, remains present somewhere in the earth. The crucial question is "where?".

The natural distribution of elements in the earth's crust is controlled by two major factors. The first is the set of ambient geological fractionating processes that leads to regions of depletion and concentration of the element. The second factor includes the overall geochemical characteristics of the element. Elements that are concentrated by a small number of fractionation processes can be expected to have a multi-modal distribution, with a peak in the tonnage versus grade curve for each of the modes of geochemical concentration. For elements having a large number of applicable concentration processes, the peaks overlap and the resulting tonnage versus grade curve takes on a log-normal characteristic. For example, the element chromium, whose distribution at high concentrations is solely governed by fractional crystallization in mafic magmas (i.e. high in magnesium and iron), one would expect a bimodal distribution of concentrations, with one peak at the average crustal abundance and the high concentration peak at the mafic fractionation concentration. On the other hand, most elements, uranium included, can undergo a wide variety of fractionating processes and deposits would be expected over a wide range of concentrations. In this latter case, the tonnage versus grade distribution would be expected to be log-normal. Bear in mind that geological conditions change over time and therefore the distribution patterns have varied with time.

Thermal models of the earth point to inevitable melting of the earth soon after its accretion due to gravitation energy and due to radioactive decay of uranium, thorium and potassium. Because of its large ionic size and heating due to radioactive decay, uranium is transferred into low melting temperature fractions and out of the earth's core and mantle into the crust. These geochemical and geophysical models predict that two thirds of initial uranium present in the earth are now concentrated in the crust, which constitutes only 0.4 % of the earth's total mass. The low uranium and high iron concentrations predicted for the earth's mantle and core have been supported by concentrations in iron meteorites and in mantle issuing from oceanic spreading zones (0.1 ppm U), compared with U concentrations in magma and crust in subduction zones (2 ppm U).

In considering uranium in particular, it is important to examine the tectonic and igneous processes that have redistributed the uranium within the crust. In the past four billion years, the most important processes are continental accretion and plate tectonics. In the accretion process, crust formed into masses of continental dimensions. In the second, continuing, process, the continental crust and the oceanic crust have taken on quite different characteristics in terms of uranium concentration.

Igneous processes

Igneous processes begin with the melting of mantle rocks at depths of 60–200 km, followed by the migration of less dense liquids to the surface. The migration of these less dense minerals to the surface is a predominant process in the formation of the continental

crust. The extruded liquid forms crust in two general locations, at mid-oceanic ridges, where the upwelling material forms new oceanic crust and in subduction zones, where the oceanic crust plunges back into the mantle, usually passing under the edge of a continent.

The behavior of uranium in igneous processes is dominated by two characteristics of the element. In the +4 oxidation state, the condition expected in the earth's mantle, the U^{+4} ion has an ionic radius of 97×10^{-12} m (picometers, pm) about the same as Na^{+1} ion (97 pm). Other ions common in the core and mantle are significantly smaller in radius: Fe^{+2} , 74 pm; Ni^{+2} , 69 pm; Mg^{+2} , 66 pm; and Al^{+3} , 51 pm. Thus, like sodium and the other large ions, uranium ions selectively enter partial melts within the mantle and are transported to the surface.

The second characteristic of uranium is its radioactivity, serving as a source of heat for melting the mantle and core. Like Th^{+4} (ionic radius 102 pm) and K^{+1} (133 pm), these heat-producing elements are readily fractionated out of the mantle and toward the surface. Deffeyes and MacGregor (1978, 1980) note that the earth would be a radically different place if the heat-producing elements had small radii, since the geothermal energy source would then be located deep within the core and the convection currents driving plate tectonics would be much stronger.

The rocks forming the oceanic crust at mid-oceanic ridges are characterized by a uniform uranium concentration of about 0.1 wppm. Conversely, the crust formed above subduction zones is characterized by uranium concentrations of about 2 wppm. The wide difference in concentration is due to the differences in the source materials and to the different chemistry. The upwelling mantle at the oceanic ridge has a uranium concentration of about 0.005 wppm, while the subduction zones have as their source material oceanic crust and bits of continental crust, with an average uranium concentration of about 0.1 wppm. The continuous upwelling at the oceanic ridges serves as a mechanism for depleting the core and mantle of uranium and incorporating that uranium in the oceanic crust. The relatively low concentration of uranium in the oceanic crust is augmented with uranium from continental runoff, which subsequently precipitates in the ocean basins. At the subduction zones, the oceanic crust is again subjected to partial melting and the uranium is again fractionated in the melt and transported to the surface.

Average vertical distribution of uranium and thorium

Thermal gradients in the continental crust are dependent on both heat emanating from the mantle and core of the earth and heat released by heat-producing isotopes within the crust. Temperature measurements as a function of depth in conjunction with measurements of the thermal conductivity of local minerals have indicated that the average continental crustal abundance of uranium decreases exponentially with an e-folding distance ("depth parameter") of 7100–10,000 m.

The anticipated variation of uranium concentration with depth is given by the equation, $U(z) = U(z=0)e^{(-z/h_r)}$ where z is the depth in m, h_r is the depth parameter (discussed below) and $U(z)$ is the concentration at depth z , in wppm. $U(z=0)$ is the average continental crustal abundance of uranium at the surface, 2.76 wppm.

This approximation is based on the presence of heat producing elements, U-238, Th-232 and K-40, in the continental crust, measurements of the thermal conductivity of the crustal materials and the linear temperature distribution with depth measured at many locations. The heat produced in the crust is divided about evenly between U-238 and Th-232, since the crustal abundance mass ratio between Th and U is 3.9 (Table 3). K-40 is about four orders of magnitudes lower, although potassium has a crustal abundance of 2.1%, since K-40 is only 117 ppm of natural potassium and the thermal energy output of K-40 is about four orders of magnitude below U-238 and Th-232, as shown by Lachenbruch (1968, 1970).

Obviously, this method assumes one-dimensional heat transport and a fairly uniform thermal conductivity, without a significant contribution from flowing fluids. A more recent review by Brady et al. (2006) provides more details on the technique.

Several measured values of the depth parameter h_r are listed in Table 4.

If we assume a depth parameter of 8500 m, based on the above data, then 11% of the crustal uranium inventory would be expected to be within 1000 m of the surface and 21% within 2000 m.

Important trends and discoveries

Concerns for the long-term sufficiency of uranium resources have been steadily alleviated over the last fifty years. The uranium mined to supply fuel for the first 40 years following the discovery of fission came primarily from deposits caused by changes in the pH and oxygen content of groundwater and the precipitation of U_3O_8 . In 1975 however, the Western Mining Corporation

Table 3 Sources of heat in the upper continental crust.

Isotope	Thermal output
U-238	0.095 mW/kg
Th-232	0.027 mW/kg
K-40	3.6 nW/kg

Table 4 Temperature distribution depth parameter.

<i>Location</i>	<i>h_r (m)</i>
Sierra Nevada	10,000
Eastern US	7,500
Norway and Sweden	7,200 ± 700
Eastern Canadian Shield	7,100 ± 1700
Canadian Appalachians	10,000 ± 2000
US Appalachians	8,100 ± 1300

Note: In the other references the depth parameter is denoted D, rather than h_r.

discovered the Olympic Dam deposit in South Australia (Schubert, 2001). Western Mining was not exploring for uranium but rather for copper. The deposit that they found has since been termed an iron oxide copper gold (IOCG) deposit, though these ore bodies contain substantial amounts of silver, uranium and the light rare earth elements (Williams et al., 2005). Today, Olympic Dam, with about two million tons of uranium reserves, represents about a third of the known uranium reserves worldwide. In addition, because the uranium is a co-product with copper, gold, silver and iron, the supply is more stable than would be the case for a uranium-only mine. Though the term “IOCG” is still only loosely defined, these deposits represent a new geochemistry in which iron oxide, either as magnetite or hematite, is the dominant gangue mineral. Other IOCG deposits have been identified in Australia, Peru, Brazil, Chile, Mongolia and Sweden.

Extraction of uranium from seawater

Uranium is present in the seawater at a fairly uniform concentration of 3 wppb. Simple calculations can indicate that this concentration is insufficient to warrant pumping seawater through an extraction plant. Various groups have, however, developed surface ligands for polyethylene fibers that effectively chelate uranium ions from seawater. The buoyant fibers, gathered together into loose bundles, are about 40 m long and anchored at a depth of 100 m, allowing 60 m for the passage of ships. The bundles of fibers are immersed for ~90 days, at which time the dry-weight of the fibers is ~0.1% uranium. The bundles are then winched aboard a service ship where the uranium is eluted with an acid solution, after which the bundles are returned to the sea. The estimated lifecycle cost of the uranium recovered in this scenario is about \$640/kg_U (Conca, 2016; Schneider et al., 2014), though more pessimistic assumptions concerning fiber/ligand lifetime, handling costs and extraction rates indicate costs of order \$1000/kg_U.

While \$640 or \$1000/kg_U is well above current uranium prices, the cost of uranium from seawater serves to place an upper limit on future prices for nuclear fuel, first because the inventory in the oceans is immense (about 4 Gt_U) and secondly because only 3% of the global population lives in landlocked countries. Thus no country or international cartel can monopolize the uranium market, as has been the case with petroleum.

To put the increased cost of uranium extracted from seawater in perspective, an increase in the price of natural uranium from the present \$56 per kg_U (i.e. \$30 per lb of U₃O₈) to \$640 per kg_U increases the cost of electricity by \$20 per MWe-hr. An increase in the cost of natural gas from the present \$2.50 per million BTU to \$5.00 per million BTU increases the cost of electricity by \$21 per MWe-hr. Reducing the tails assay after enrichment would decrease the impact of seawater extraction, even accounting for the added additional enrichment costs.

Conclusions

Thus, considering these trends and discoveries, one can have confidence that uranium and thorium will not be a limitation on the sustainability of nuclear energy. We do not know today the exact locations of the ore bodies containing future sources of uranium and thorium, but the global measurements of supernova nucleosynthesis, geoneutrinos and thermal gradients discussed in this article indicate that those sources are very likely to exist. Furthermore, it is not necessary that we know those precise locations today since the fuel itself will not be needed for several centuries.

The geoneutrino measurements indicate that at least 25% of global uranium and thorium are located in the continental crust and the thermal gradient data indicate that these elements are within a few kilometers of the surface. The discoveries of unexpected IOCG deposits indicate that multiple modes for the concentration of uranium exist.

The development of chelating ligands for the extraction of uranium from seawater is not yet economical compared to existing mines and *in situ* extraction on land, but the technology places a ceiling on future uranium prices and assures a widely accessible source. Although the quantity of uranium in the oceans is immense, hundreds of times presently identified resources, the oceans are being constantly replenished by rivers which carry dissolved uranium from the continental crust.

Glossary

BTU *British Thermal Unit* ($= 1055 \times \text{joule}$), MMBTU is 1 million BTUs.

CRF *Capital recovery factor* is the (annual) rate at which capital expenditures financed with debt and equity capital are paid to banks and investors.

D&D *Decontamination and demolition (decommissioning)* is the process by which an operating facility site is returned to its original state before operations. This involves the decontamination of contaminated structures and equipment, the removal of equipment, and the demolition of structures. Under different regulatory regimes this leads to the end (“decommissioning”) of the operating license.

Debt Two forms of debt are (1) a loan from a financial institution and (2) sales of bonds to investors. Both involve repayment of principle and *interest*. Both forms are repaid before payments to equity providers in the case of bankruptcy (which involves the restructuring of assets and liabilities).

Equity At least two forms of equity are (1) funds provided by the owner/operator out of earnings and (2) funds provided by investors hoping for a *rate of return* from profits.

FOAK *First-of-a-kind* technology refers to the set of early (“first”) units over which design and licensing costs can be recovered, justifying the construction of dedicated manufacturing facilities.

GIF *Generation IV International Forum* is a group of countries working together to develop advanced reactor technologies, known as “fourth generation” technologies.

IDC *Interest during construction* is the amount of financing charges (interest and returns to equity) that accumulate during the construction of a facility.

Interest rate Is the rate of return required by banks or on bonds, see *debt*.

LC *Levelized cost* is the value that equates (1) the discounted costs of a facility over its lifetime, including expenditures during construction and decommissioning with (2) the discounted revenues of a facility’s lifetime.

LCOE *Levelized cost of electricity* is the lifetime levelized cost of a generated megawatt-hour.

Nominal Is the cost or price of a good or service in the year of currency when expended.

PPI *Producer Price Index* is a measure of inflation relevant to producers, similar to the CPI, the Consumer Price Index, which is a measure of inflation facing consumers.

Real Is the nominal cost or price of a good or service inflated or deflated, e.g., by the PPI, to a currency in a particular year, e.g., 2018.

SMR *Small modular reactors* refers to nuclear power reactors (not plants) less than 300 MW that can be manufactured in a dedicated facility and shipped to a licensed power plant site.

Introduction

One of the issues challenging nuclear energy is its competitiveness with other forms of electricity production, such as coal, natural gas, and renewables. Because climate change requires moving away from fossil fuels to clean energy alternatives, such as wind and solar, nuclear energy (the largest source of carbon-free electricity) faces competitive challenges from low-priced natural gas,

*Retired.

subsidies for renewables, state policies that mandate new renewable plants despite their cost, and liberalized market policies regarding the dispatch of power based on variable cost.

This article reviews the current economics of nuclear versus other electricity generating alternatives. The future of nuclear energy depends on whether markets value the long-term investment that nuclear energy represents and on whether regulators allow this value to be represented in the market-based prices that utilities can charge. The nature of nuclear energy is that it is a “base load” supplier of power on a 24-h/365-day basis. This is in contrast to the hourly variability of solar and wind, and the need for backup power when the wind does not blow, or the sun does not shine. Pricing of these alternatives and economic comparisons do not consider the cost of backup power under such circumstances. This article focuses on the basic cost of power (the cost of delivering power to the grid, or “bus bar”) coming from each of the sources without considering system effects or grid reliability. For these, see Rothwell (2021b).

Levelized cost of electricity (LCOE) is an important measure for comparing nuclear energy with other forms of electricity generation. See Rothwell (2021a) for more details regarding the economics of nuclear energy. The LCOE is a measure of discounted life-time costs averaged over discounted electricity revenues. *LCOE* (note: variables are in italic and parameters are in bold) can be defined as in NEA/IEA (2015, p. 28):

$$LCOE = \sum_t [(I_t + O\&M_t + F_t)/(1+r)^t] / \sum_t [E_t/(1+r)^t] \quad (t = -LT, \dots, T), \quad (1)$$

where

I_t are investment expenditures (including decommissioning costs) in year t ,

$O\&M_t$ are Operations and Maintenance expenditures (including refurbishments) in year t ,

F_t is the product of fuel expenditures, F_{MWh} , and E_t in year t , including a fee for spent nuclear fuel, SNF, management and disposal, r is the discount rate (a parameter) and $(1+r)$ is the discount factor, e.g., $(1+5\%)$,

E_t are the MWh of electricity generated in year t , and

LT is the construction lead time.

The summations in Eq. (1) run from (1) the start of large construction expenditures when the foundation is poured ($t = -LT$, the construction lead time) to the start of commercial operation ($t = 0$) and (2) from the start of commercial operation to the end of commercial operation, T , the life of the plant. (There is a third period from the end of the commercial life to the end of decommissioning; the cost of which is treated as a capital cost or as a contribution to a sinking fund accounted for in $O\&M$.) The discount rate is used to estimate how much the project’s future (or past) cash flows (expenditures or revenues) would be worth at a specific time, such as, $t = 0$, the present. At a discount rate of 5%, an $O\&M$ expenditure of \$1,000,000 in $t = 2$ would be $\$1,000,000/(1.05)^2 = \$907,029$. See Rothwell (2021b).

In this discussion, a distinction must be made between nominal and real values. Nominal prices and costs are those in the currency of the year of the expenditure. Real prices and costs are those in the currency of a specific year (here, prices are in 2018 USD). (Prices are determined in markets; costs are the resources required to produce commodities and services traded in markets.) Here, nominal prices are deflated (inflated) to real prices with the Producer Price Index (PPI), see Federal Reserve Bank of St. Louis (2019). It is often difficult to tell in the literature whether prices and costs are in nominal currency or in real currency, if not explicitly stated. Because taxes are assessed on, and budget outlays are stated in, nominal values, most cost estimates associated with governmental or regulatory oversight are in nominal currency. This article uses real prices and costs. However, the PPI increased an average of 5.7% per year from 2000 to 2008, then experienced an average of 0% from 2008 to 2018 (the average from 2000 to 2018 was 2.6%). This means that cost estimates made before July 2008 should be discounted by the PPI, but cost estimates after July 2008 are *similar* to what they would be in 2020 (ignoring real escalation and real changes in the costs of construction, $O\&M$, and fuel).

Examples of electricity levelized costs can be found in NEA/IEA (2015). Table 1 presents levelized costs for nuclear power plants (NPPs). In each case the investment cost (construction cost plus financing cost) is the largest component of NPP LCOE. Investment costs are lowest in East Asia. The $O\&M$ cost (which is dominated by the cost of labor, see NEA/IAEA 2018) is less than the fuel cost for Chinese and Korean NPPs and greater than the fuel cost for European and US NPPs. LCOE is lowest in China and Korea, about the same in the United States, Continental Europe, and Japan, and highest in the United Kingdom.

To provide a historical context consider the types of nuclear power plants constructed since 1951. Nuclear power plants can be classified by means of a few characteristics, as in Fig. 1. First, a reactor has either a “fast” or “slow” chain reaction. There have been 12 fast power reactors built or under construction. Second, thermal reactor technologies (with “slow” chain reactions) can be characterized along two dimensions: (a) the choice of nuclear reaction moderator, to capture nuclear particles; and (b) the choice of nuclear reactor coolant, to remove heat. To moderate and control the chain reaction, light water (H_2O), heavy water (D_2O , in which deuterium, D , has twice the mass of hydrogen), or graphite (carbon) are used. Coolants are either water (light or heavy) or gas (air, carbon dioxide, or helium). (For compatibility with IAEA, 2019, 2020, two demonstration reactors are included in Fig. 1: the organic [hydrocarbon] cooled and moderated reactor, OCMR, and the liquid-metal cooled and graphite-moderated reactor, LMGMR.) Table 2 looks more specifically at light and heavy water nuclear power plants. Most under construction are PWRs (pressurized water reactors) and most of these are Russian (VVERs, Rosatom, 2018), Chinese (many models), and Korean (APR1400), some of which have been under construction for 10 years or more. Many American and French nuclear power units have been operating for more than 33 years (the median age of all units). On the profitability of NPPs in the United States, see UCS (2018).

Section “Components of the levelized cost of electricity” of this article discusses the components of levelized cost. Section “Comparisons of nuclear generation costs with other power generating technologies” compares the levelized costs of nuclear power with Combined Cycle Gas Turbines (CCGT) burning natural gas, coal, geothermal, photovoltaic solar, concentrating solar, onshore and offshore wind, and hydropower. Section “Observations on the past and future of the nuclear power industry” offers observations on the future of commercial nuclear power.

Components of the levelized cost of electricity

Fixed costs: Generating plant construction and its financing costs

Levelized capital cost, LKC, is a function of total capital investment cost and the cost of capital:

$$LKC = KC\{OC(MW) \cdot [1 + IDC(r, LT)]\} \cdot CRF(r, T)/E, \quad (2)$$

Table 2 Commercial light and heavy water reactors in 2020.

where

KC is the total capital investment cost, a function of OC (see Rothwell, 2021a),

OC is overnight cost, including contingency, a function of size, MW,

MW is the size of the plant in net megawatts-electric,

IDC is the rate of Interest During Construction to finance KC , a function of r and LT ,

r is the appropriate real cost of capital,

LT is the construction lead time,

T is the economic life of the facility,

CRF is the capital recovery factor, a function of r and T , see Rothwell (2021b), and

E is the annual electricity output expressed in megawatt-hours (MWh).

Construction cost, KC , is the total amount spent on construction and testing before any electricity or revenues can be generated (as defined in GIF/EMWG, 2007, p. 79). KC is equal to the overnight construction cost with contingency plus financing costs, as measured by IDC . To measure these consistently, a set of standard definitions of construction accounts, structures, equipment, and personnel is required. The Code of Accounts (COA) used here is derived from the *Cost Estimating Guidelines for Generation IV Nuclear Energy Systems* (GIF/EMWG, 2007), developed by the Economic Modelling Working Group (EMWG) of the Generation IV International Forum (GIF). While applied to the cost of nuclear power, with the GIF COA any electricity generating technology can be characterized by this COA. The total capital investment cost, KC , includes:

- Account 20, Direct construction costs plus Account 10, which includes pre-construction costs, i.e., those costs before the first concrete is poured for the foundation.
- Account 30, Indirect costs include engineering and administrative costs that cannot be associated with a specific cost category in Account 20.
- Account 40, Owners' costs include expenses incurred by the owner(s) associated with the plant and plant site, but not including off-site transmission system costs; the owners' costs associated with the development of the site, e.g., US Environmental Protection Agency (EPA) licensing fees.

A technology appropriate contingency is added to direct, indirect, owners' plus any supplemental costs. And to these accounts is added "Interest During Construction," IDC , expressed as a percentage mark-up on overnight costs, known as the "IDC factor."

The sum of Accounts 10–50 is the base overnight construction cost, $BASE$. Table 3 portrays the estimated costs of a System 80+, which was based on the System 80 design used at Palo Verde Units 1, 2 and 3, the largest NPP in the United States. The term "overnight" is used to describe what the construction cost would be if money had no time value. $BASE$ plus contingency, CN , equals total overnight cost, OC . Some references define OC without contingency and some references define overnight cost with contingency, as does the US Energy Information Administration (US EIA, 2019), see below. To make this distinction, $BASE$ excludes contingency and OC includes contingency. OC plus Account 60, IDC , equals total capital investment cost, KC . To understand the relationship between lead time and compounding IDC , see Rothwell (2021b). Although usually not a part of KC , "decontamination and dismantling" (D&D) costs must be set aside before or during operation for plant D&D after operation. In the latter case, D&D funding is treated as a sinking fund (and is assigned to O&M costs, see next section). (D&D cost might not include decontamination if hazardous materials have not been used.)

Table 3 Construction cost estimates for a single unit of a twin PWR in the United States.

COA	System 80+ General description	Cost USD-2018 (in millions)	Cost USD-2018 (per kWe)
20	Capitalized direct costs	\$2626	\$2296
30	Capitalized indirect costs	\$1556	\$1360
40	Capitalized owner's cost	\$486	\$425
	Base construction costs (<i>BASE</i>)	\$4668	\$4081
	Contingency (20% of <i>BASE</i>)	\$904	\$791
	Overnight construction cost	\$5573	\$4871
60	Capitalized financing costs (<i>IDC</i>)	\$1062	\$929
	Total capital investment cost (<i>KC</i>)	\$6635	\$5800
	Annual payment to capital (5% for 60 years)	\$351	
	Annual generation with 85% capacity factor (GWh)	8524	
	Levelized capital cost (<i>LKC</i>)	\$41.12	

Note: Cost have been increased from ORNL (2011, p. 81) with a 2% real annual escalation rate for NPPs not yet under construction.

Based on ORNL (2011) *Advanced High Temperature Reactor Systems and Economic Analysis*. ORNL/TM-2011/364, prepared by Oak Ridge National Laboratory under the direction of UT-Battelle, Oak Ridge. <http://info.ornl.gov/sites/publications/files/Pub32466.pdf>.

Variable costs: Operating and maintenance and fuel

This section discusses operations and maintenance (O&M) and fuel costs; for more details see Rothwell (2021a). While O&M costs can be treated as variable costs, for many generating technologies some O&M costs are fixed, and some vary with output. For this reason, US EIA (2019) gives both "Variable O&M" in \$/MWh and "Fixed O&M" in \$/kW per year. Given the LCOE is in dollars per MWh, Fixed O&M must be converted into \$/MWh as a function of the capacity factor and generator capacity:

$$O\&M_{MWh} = \text{Variable O\&M} + (\text{Fixed O\&M} \times 1,000)/(CF \times 8766), \quad (3)$$

where

$CF \equiv E/(MW \times 8766)$. In Table 6 (below), the assumed Variable O&M for an NPP is \$2.37/MWh, the assumed Fixed O&M is \$103.31/kw per year, and the assumed capacity factor is 85% (Table 5). $O\&M_{MWh}$ is equal to $\$2.37 + (\$103.31 \times 1000)/(0.85 \times 8766) = \$2.37 + \$13.87 = \$16.24/\text{MWh}$ (Table 7). On the other hand, Table 4 shows annual capital and O&M cost estimates from ORNL (2011, p. 81). In this estimate annual O&M costs are approximately \$19/MWh. Other discussions of the relationship between staff size (the largest component of O&M) and O&M can be found in Rothwell (2016, Section 4.3) and NEA/IAEA (2018, Chapter 2). Annual fuel and irradiated fuel management costs are added to Table 4 next.

Second, consider levelized fuel costs over the life of the NPP and fuel expenditures in each year. The cost per MWh of LEU fuel, F , is

$$F_{MWh} = [FC/(\epsilon \cdot \text{BURN} \cdot 24)] + \text{SNF}, \quad (4)$$

where

FC is the cost of nuclear fuel in USD per kilogram of uranium (USD/kgU),

ϵ is the thermal efficiency of converting MW-thermal into MW-electric,

BURN is the burnup rate measured in thermal megawatt-days per kgU,

24 is the number of thermal MWh in a thermal megawatt-day,

E are the MWh of electricity generated in year t , and

SNF is the interim storage cost of Spent Nuclear Fuel per MWh (assumed to be \$1.33/MWh real) plus geologic disposal costs (assumed to be \$1/MWh real).

Table 4 Levelized cost of electricity estimates for a generic PWR unit in the United States.

System 80+ PWR 4-loop	2018\$
Annual capital costs per MWh	\$41.12
Annual D&D contributions per MWh	+\$2.15
Annual O&M costs per MWh	+\$18.87
Annual fuel and SNF management costs per MWh	+\$7.33
Levelized costs of electricity per MWh	=\$69.47

See text.

For example, if the burnup rate is 50 MW-days per kgU and the efficiency is 33.3%, then the cost of fuel per MWh is (1) the cost of fuel per kgU divided by $[50 \text{ MWth-days} \times 24 \text{ h per day} \times 0.33 \text{ MWh per MWe}] = 400 \text{ MWh}$ plus (2) the cost of irradiated fuel management and disposal, assumed here to be \$2.33 from NEA/IEA (2015, pp. 32–33). If the cost per kgU is \$2000, then F_{MWh} equals \$5/MWh plus \$2.33/MWh, or about \$7.33/MWh. (Fuel prices in NEA/IEA, 2015, were estimated in 2014 when both the prices of natural uranium and SWU were higher, i.e., the implicit assumption in NEA/IEA, 2015, is that the cost of nuclear fuel per kg is \$2800 for fuel with a burnup of 50 MW-days per kgU.) Table 4 adds NPP fuel costs to capital and O&M costs.

While construction and O&M costs follow the same structure for electricity generators other than nuclear power, fossil fuel costs are calculated with a different formula. Here, the cost of fuel for a MWh generated with natural gas in a CCGT is given (this is applicable to all fossil fuels):

$$F_{\text{CCGT/MWh}} = [(P_{\text{NGAS}} \cdot \text{HR}_{\text{CCGT}})/1000] + (P_{\text{CO}_2} \cdot \text{CO}_{2\text{CCGT}}), \quad (5)$$

where

$F_{\text{CCGT/MWh}}$ is the cost of natural gas per MWh,

P_{NGAS} is the price of natural gas in \$/MMBTU,

HR_{CCGT} is the heat rate (in BTU/kWh) for CCGTs,

P_{CO_2} is the fee for emitting a tonne of CO_2 , and

$\text{CO}_{2\text{CCGT}}$ is the tonnage of CO_2 produced by the CCGT unit per MWh, known as the “carbon intensity factor.”

For example, if (1) the price of natural gas is \$5.50/MMBTU, (2) the heat rate is 6200 BTU/kWh, (3) the carbon intensity factor is 0.330, and (4) the price of a tonne of CO_2 is assumed to be \$30.00, then the cost of natural gas per MWh is \$34.10 without a carbon fee and is \$43.99/MWh with a carbon fee. These costs are explored for other electricity generators in the next section and a sensitivity analysis is conducted on the volatile price of natural gas.

Comparisons of nuclear generation costs with other power generating technologies

This section compares nuclear generation costs with other electricity generating technologies following the assumptions in US EIA (2019) and in NEA/IEA (2015), in anticipation of the publication of the next edition of this report: *Projected Costs of Generating Electricity, 2020 Update*. The 2020 edition will survey NEA and IEA member country experts regarding their expectations of the costs of generating electricity in 2025 (not all member countries submit fully completed surveys). One of the primary differences in the 2010 report (NEA/IEA, 2010) from the 2015 report was the use of 5% and 10% as discount rates in the 2010 report and 3%, 7%, and 10% in the 2015 report, making direct comparisons between the two reports at 3%, 5%, and 7% difficult. To simplify the discussion here a 5% discount rate is used. (On the sensitivity of the competitiveness of nuclear power to the assumed cost of capital, see Rothwell 2021b.)

To compare the projected costs in Table 1 with those of other electricity generating technologies, Table 5 gives default values for construction lead times (LT) and lifetimes (T) from NEA/IEA (2015). Where country survey data was provided for contingency percentage rates, the country data was used. As stated in NEA/IEA (2015, p. 31), “the following conventions have been adopted [for contingency rates] if national data were not available: (1) nuclear power: 15% of overnight costs, and (2) all other technologies: 5% of overnight costs.” These assumptions did not follow published guidelines (as discussed in Rothwell 2021a) and were determined through debate among the member country experts.

Also, there is little guidance regarding appropriate end-of-life costs (NEA/IEA, 2015, p. 33):

Table 5 Default assumptions for cost projections in NEA/IEA (2015).

Electricity generating technologies	Lead time (years)	Life-time (years)	Contingency (%)	Decommissioning (% of OC)	Capacity factor (%)
Nuclear	7	60	15%	15%	85%
Combined cycle natural gas turbines (CCGTs)	2	30	5%	5%	85%
Coal	4	40	5%	5%	85%
Geothermal	1	40	5%	5%	80% ^a
Solar (photovoltaic, PV)	1	25	5%	5%	14% ^a
Solar (concentrating solar power, CSP)	1	25	5%	5%	25% ^a
Wind (onshore)	1	25	5%	5%	28% ^a
Wind (offshore)	1	25	5%	5%	40% ^a
Hydropower	Survey	80	5%	5%	68% ^a

^aData from survey of United States in NEA/IEA (2015, Chap. 3).

Based on NEA (Nuclear Energy Agency) and IEA (International Energy Agency). (2015) *Projected Costs of Generating Electricity, 2015 Update*. Paris: OECD. <https://www.oecd-nea.org/ndd/pubs/2015/7057-proj-costs-electricity-2015.pdf>, pp. 30–34.

"At the end of a plant's lifetime, decommissioning and waste management costs are spread over a period of ten years for all technologies. In case of any positive 'residual value' after the operating lifetime of a plant (iron scrap value, left-over carbon permits, etc.), there was a possibility to also report it. For fossil fuel plants, the residual value of equipment and materials is assumed to be equal to the cost of dismantling and site restoration, resulting in a zero-net cost of decommissioning. For wind turbines and solar panels, rather than decommissioning, what takes place in practice at the end of their operating lifetime is a replacement of equipment, and the scrap value of the renewable installation is estimated to amount to 20% of the original capital investment. However, no country reported such residual values."

Because no country surveyed reported such residual values, an assumption was made that the end-of-life costs would be equal to those in [Table 5](#). Because these costs were discounted at the same rate as the cost of capital (3%, 7%, and 10%), annual contributions to end-of-life funds were mute (usually much less than \$0.25/MWh at 7% and 10% discount rates). See discussion of the appropriate discount rate in [NEA \(2018a\)](#).

Regarding capacity factors, [NEA/IEA \(2015, p. 31\)](#) states, "a standard capacity factor of 85% was used for all CCGTs, coal, and nuclear plants under the assumption that they operate in baseload. While it is clearly understood that many CCGTs are frequently used in mid-load or even peak load rather than in baseload, since the overarching concern here is with baseload capacity, the 85% assumption is also used as a generic assumption for CCGTs." Capacity factors for other technologies were taken from country surveys. The capacity factors for renewables varied enormously across countries. Therefore, [Table 5](#) gives capacity factors for various renewables (including hydro) for the United States, corresponding to expected costs in [Table 6](#). Generally, no storage costs are added to the costs of generating electricity if the capacity factor is less than what might be expected for a baseload technology given that each technology is dispatched in a electricity system as a function of its fixed and variable costs; see discussion in [Rothwell \(2021b\)](#).

Default fuel prices are given in [NEA/IEA \(2015, pp. 32–33\)](#). For the United States, hard coal is assumed to have a price of \$101/t (USD 2013 = USD 2018), and natural gas is assumed to have a price of \$5.50/MMBTU (USD 2013 = USD 2018), both are assumed to have a carbon tax of \$30/t of CO₂. Nuclear power is assumed to have the following once-through fuel cycle costs across the world (unless given in a country's survey):

"For uranium prices, an indicative value that does not directly enter the calculation of the front end of the nuclear fuel cycle is USD 100/kg of U₃O₈, which has been the average price during the last half century (1) Front end of nuclear fuel cycle (mining, enrichment, conditioning): USD 7.00/MWh and (2) Back end of nuclear fuel cycle (spent fuel removal, disposal and storage): USD 2.33/MWh".

For the United States, assumptions in [NEA/IEA \(2015\)](#) are updated using the assumptions in [US EIA \(2019\)](#). [Table 7](#) compares levelized cost of ("Advanced") CCGT, ("Advanced") Nuclear, ("On-shore") Wind, and (fixed-tilt) Solar PV as defined in US EIA (2019), supplemented with assumptions from US EIA (2016), [NEA/IEA \(2015\)](#), and calculations as in [Rothwell \(2016\)](#). (See [NEA, 2018b](#), comparing the costs of pollutants from each of these generating alternatives.) At \$5.50 per MMBTU, CCGT is the cheapest alternative. The levelized cost of nuclear and onshore wind are approximately the same. Solar PV is significantly higher due to its low capacity factor. These levelized costs are based on published assumptions and depend on the price of natural gas.

Because many renewables are dispatched when they generate electricity, their non-economic introduction into liberalized markets can create unanticipated load and profitability losses. As explained in [NEA \(2018b, p. 82\)](#), based on information from [NEA, 2012](#)):

"it should be recognized that the recent rapid deployment of subsidized [Variable Renewable Energy] in many OECD countries has had a profound impact on the electricity market, in particular contributing to a sharp decrease of wholesale electricity prices and to an increase of their volatility. This, in

Table 6 US Energy Information Administration costs of new generating stations.

Electricity generating technology	Size (MW)	Lead time (years)	Contingency	Over night (\$2018/kW)	Variable O&M (\$/MWh)	Fixed O&M (\$/kW/year)

Based on data from NEA (Nuclear Energy Agency) (2012) *Nuclear Energy and Renewables: System Effects in Low-carbon Electricity Systems*. Paris: OECD. <http://www.oecd-neo.org/ndd/pubs/2012/7056-system-effects.pdf>, p. 136.

turn, has severely affected the revenue stream and the profitability of incumbent utilities, thus jeopardizing their financial stability and their ability to take on new investments. The short-term impact on market prices has been, by far, the most acutely felt by the industry... The combination of a reduced capacity factor and reduced electricity prices may have a severe impact on the revenues of existing generating plant, ... as shown in [Table 8].”

To understand the influence of natural gas prices, Fig. 2 (based on US EIA, 2014, US EIA, 2015, and updated with information from Federal Reserve Bank of St. Louis, 2020) presents three US natural gas price series: (1) interpolated monthly Texas natural gas prices (from annual data) for electric utilities from 1970 to 2012 from the US EIA’s SEDS for Texas; (2) the monthly US natural gas wellhead price from 1977 to 2014; and (3) monthly Henry-Hub spot-market prices in Louisiana from 1994 to 2020. Although most CCGT generators have long-term fuel supply contracts, the opportunity cost of using their contracted natural gas for electricity generation is the spot price. For this reason, this price is used to convert the price of natural gas into the price of electricity.

Comparing these results with the calculations in Tables 1 and 7, new nuclear was competitive with natural gas CCGT between 2000 and 2008. However, new nuclear cannot compete with natural gas prices below \$4/MMBTU (Table 9) in deregulated markets

Fig. 2 Natural gas prices, 2018 US\$/MMBTU, 1970–2020. Data from US EIA (Energy Information Administration) (2014) *State Energy Data System (SEDS): 2013 Updates by Energy Source*. US EIA. <http://www.eia.gov/state/seds/seds-data-fuel.cfm?sid=US>; US EIA (Energy Information Administration) (2015) *Monthly U.S. Natural Gas Wellhead Price*. US EIA. <http://www.eia.gov/dnav/ng/hist/n9190us3m.htm>; Federal Reserve Bank of St. Louis (2020) *Henry Hub Natural Gas Spot Price*. <https://fred.stlouisfed.org/series/DHHNGSP>.

Table 9 Levelized cost for new natural gas generation, 2018 US\$, $r = 5\%$.

Combined cycle gas turbine (CCGT)		CCGT	CCGT	CCGT	CCGT
Levelized cost (2018 dollars)	$r =$	5.0%	5.0%	5.0%	5.0%
Fuel price	\$/MMBTU	\$2.00	\$4.00	\$6.00	\$8.00
Levelized capital cost (fixed)	\$/MWh	\$7.45	\$7.45	\$7.45	\$7.45
Levelized O&M cost (variable)	\$/MWh	\$3.44	\$3.44	\$3.44	\$3.44
Levelized fuel (variable)	\$/MWh	\$12.40	\$24.80	\$37.20	\$49.60
Levelized fuel CO ₂ fee (variable)	\$/MWh	\$9.89	\$9.89	\$9.89	\$9.89
Levelized variable cost	\$/MWh	\$15.84	\$28.24	\$40.64	\$53.04
Levelized cost without waste fee	\$/MWh	\$23.29	\$35.69	\$48.09	\$60.49
Levelized cost with waste fee	\$/MWh	\$33.18	\$45.58	\$57.98	\$70.38

Based on calculations in Table 7.

in the United States: it is unlikely that revenues would cover the fixed costs of NPP construction. Even if there were carbon taxes of \$30/tCO₂, new nuclear would not be competitive outside of China and Korea. If existing nuclear O&M and fuel costs are similar to new nuclear O&M and fuel costs (i.e., construction costs have been paid off for plants older than 30 years), existing NPPs could be competitive with CCGT with natural gas prices above \$4/MMBTU. However, with natural gas prices bouncing between \$2 and \$4/MMBTU, it would be difficult to justify investment in upgrades, uprates, or life extensions without the certainty that these investments could be recovered. On the other hand, natural gas prices have generally been twice as high in Europe and three times as high in Japan, see Knoema (2019). Therefore, it is more likely that incremental investments and new nuclear power could be justified in Continental Europe assuming rising natural gas prices and carbon taxes.

Finally, the various prices in Tables 1, 7, and 9 can be compared to wholesale electricity prices in the United States. Fig. 3 (based on information from US EIA, 2020) gives an approximation of daily electricity prices across the United States. (Day-ahead prices are the prices bid into the electricity market for the next day; see Section 3, “Competition on the Transmission Grid: Regulated Tariffs Versus Market Pricing” in Rothwell 2021b.) Because these are monthly averages, the daily highs and the lows have been averaged out. Only part of the time will electricity generated by new nuclear, new wind, and new solar-PV be adequately compensated. As explained in US EIA (2020):

“Wholesale electricity prices at several major hubs were generally lower in 2019 than in 2018, except in Texas. Record-high electricity demand in the summer led to much higher 2019 wholesale electricity prices in the Electric Reliability Council of Texas (ERCOT) electricity market. Day-ahead, around-the-clock wholesale electricity prices averaged \$38 per MWh in ERCOT in 2019, up 13% from their 2018 average. At other representative hubs—such as those in the Independent System Operator of New England (ISO-NE), New York Independent System Operator (NYISO), and PJM [Pennsylvania-New Jersey-Maryland] Interconnection—annual average wholesale electricity prices were generally 15% to 30% lower than in 2018. Much of this decline in wholesale electricity prices was the result of lower natural gas prices in 2019.”

Fig. 3 Monthly average day-ahead prices in selected US electricity markets, 2018–2019. Data from US EIA (Energy Information Administration) (2020) *Wholesale Electricity Prices Were Generally Lower in 2019, Except in Texas*. (January 10). <https://www.eia.gov/todayinenergy/detail.php?id=42456#>.

Therefore, only natural gas with prices less than \$4/MMBTU without carbon taxes can be effectively compensated, as shown in Table 9. (Of course, this is because electricity generated by natural gas sets the price in most electricity markets in the United States.)

Observations on the past and the future of the nuclear power industry

As utilities shut down coal burning plants in response to political pressure, they tend to replace them with natural gas because in deregulated systems the market price is generally determined by the price of natural gas, so the lowest risk alternative to select is CCGT. Thus, competitiveness of nuclear power in the United States (and in some regions of the world) is a function of the price of natural gas. In areas of the world that must import much of their natural gas as liquefied natural gas and where NPP construction costs are relatively low (in China and in Korea), new nuclear power is competitive with alternatives, particularly if CO₂ fees are added. In Continental European countries and Japan that must import their natural gas, new nuclear power can be competitive, particularly if financing is available. In North America, the “fracking” of natural gas has led to an oversupply, a decline in electricity prices, and a difficult economic environment for both existing and new NPPs. The United Kingdom imports one-half of its natural gas as the North Sea reserves are being depleted. In response to this depletion and the aging of its NPP fleet, the United Kingdom seems to be willing to pay the highest prices for new NPPs.

While NPPs are closing in Europe and the United States, China and Russia are building much of the new NPP capacity. Hence, the center of the NPP industry is moving eastward from Europe and westward from North America and Japan. Russia is encouraging orders of its various models of VVERs with financing and the provision of both front and back end nuclear fuel services, e.g., the take-back of used nuclear fuel for reprocessing in Russia. The Chinese have been slower to export their nuclear units. However, China hopes to export its Hualong One (HPR1000) NPP, now being constructed in China. The Chinese are able to build their NPPs on time: (1) they started building their French EPRs in Nov 2009 and April 2010, and finished them in June 2018 and June 2019, surpassing the French in Finland (started in August 2005) and France (started in December 2007), and (2) they started building their Westinghouse AP1000s in March and December 2009 and finished them in June and August 2018, well ahead of the AP1000s at Vogtle (as yet incomplete) and Summer (since suspended). In both cases they passed ahead of the construction of the “First-of-a-Kind” (FOAK) units in home countries, showing the path to completion for Western Europe and the United States. Areva announced its reorganization in June 2016 and Westinghouse filed for bankruptcy in March 2017.

The US Government (USG) through the US Department of Energy (US DOE) tried to encourage the construction of NPPs in the United States in the early 2000s. US DOE engaged in a series of programs to provide incentives for new nuclear investments. It was envisaged that these programs would result in new NPPs operating in the United States by 2010 (Johnson, 2002, p. 2): “Goals: [1] Orders for one or more new nuclear plants by 2005 [and 2] Operation of new nuclear power plants by 2010.” However, electric utilities did not order new NPPs until after the passage of the US Energy Policy Act of 2005.

Three provisions in the 2005 Act promoted new nuclear capacity construction: production tax credits (PTCs), a standby support program (SSP), and loan guarantees (see Rothwell, 2016, Table 2.5). The subsidies were disproportionately granted to the first half-

dozen plants built and only to those that applied for Construction and Operating Licenses (COLs) before 31 December 2008. Within this group, there was a set of four AP1000s: Vogtle Units 3 and 4 (started in 2011), and Summer Units 2 and 3 (started in 2012). The FOAK units do not necessarily refer to the very “first” unit(s), but the set of first units over which design and licensing costs can be recovered, which justifies the construction of dedicated manufacturing facilities. While the PTC program was intended to support new nuclear operation (by means of tax reductions, if the units were in commercial operation by January 2021) and the SSP was intended to stabilize the new nuclear licensing process (by means of financial support during unforeseen regulatory delays), the US DOE loan guarantee program was intended to promote carbon-free emissions in electricity production from low-carbon energy technologies, including new nuclear capacity. Under this program, the total loan guarantee amount was limited to congressional appropriations. The borrower must pay fees for these loan guarantees that are similar to those that international financial markets would charge for similar loan guarantees.

The Energy Policy Act of 2005 plus various appropriations bills set the total amount of the loan guarantee program for advanced nuclear plants at \$18.5B. The owner-investors in Vogtle Units 3 and 4 were provisionally offered a loan guarantee of \$8.3B. After 4 years of negotiations, in February 2014, the US DOE awarded Vogtle co-owners Georgia Power and Oglethorpe Power with a \$6.5B loan guarantee and with a loan guarantee of \$1.8B to the remaining co-owner, the Municipal Electric Authority of Georgia. (US DOE provided an additional \$3.7B loan guarantee for Vogtle in March 2019, for a total of \$12B.) To follow the progress at Vogtle, see ANS (2020).

The US DOE gave three other plants positive initial reviews: Summer Units 2 and 3 (AP1000s) with South Carolina Electric & Gas (SCE&G), Calvert Cliffs Unit 3 (a single EPR) with Constellation in Maryland, and South Texas Project Units 3 and 4 (ABWRs) with NRG Energy in Texas. Even with loan guarantees, the builders of new nuclear would be required to convince Wall Street that investing in nuclear generation did not involve more risk than similar investments. In 2011 Moody's (2011) wrote (referring to SCE&G, and updating its 2007, 2008, and 2009 reports), “Today’s downgrade of SCE&G’s senior unsecured and [SCE&G] to Baa2 ... consider[ing] the heightened risk associated with a large nuclear construction program extending through 2019 that is expected to be about 50% debt financed and will pressure future financial metrics.” None of these projects received a US DOE loan guarantee. Until Vogtle 3&4 are finished, it is unlikely that the USG will subsidize large NPPs. US DOE has turned its attention to supporting Small Modular Reactors (SMRs); see Rothwell (2016, pp. 91–100), NEA (2016), Energy Strategies (2019), and Ingersoll (2021).

One of the leading SMR contenders is NuScale Power with a 12-module SMR where each module has a 60-MW (gross, 57 MW net) integrated PWR with an off-the-shelf turbine-generator and condenser. Table 10 (based on NuScale Power, 2015) reports the list price of the first two modules plus the balance of plant (BOP). Note, “The amounts shown for the individual module costs for modules 3 through 12 do not include any attributable installation labor ...” and “The lead time for ordering modules is approximately 5 years.” Unless most of the modules are installed, the NuScale SMR (as estimated in Table 10) might not be competitive with larger NPPs. Further, before seeing them in operation, it is difficult to predict their O&M costs. Therefore, it might be too early to understand the economics of SMR construction and operation.

Depending on the country and its policies regarding clean energy, nuclear power can be competitive. The low price of natural gas in the United States greatly limits the potential for new, large baseload plants due to the high initial capital investment, long construction times, and high financing costs. Although nuclear plants are a long-term investment, 60 years and possibly longer, levelized cost analysis using a single discount rate does not give credit to such investments. Some countries and states provide clean air credits for renewable energy projects, but few provide similar credits to nuclear plants. At present, China and Russia are expanding their nuclear fleets, but elsewhere, as in Europe and the United States, nuclear plants are being retired and few new plants are being built. For this situation to be reversed, new policies, designs, and construction techniques must be developed, such as inexpensive SMRs, to improve the competitiveness of nuclear with other sources of electricity.

Table 10 NuScale Power Small Modular Reactor Cost by Reactor Module.

<i>Systems installed</i>	<i>Cost</i>	<i>Net plant output (MWe)</i>	<i>Gross plant cost (kWe)</i>
All BOP plus Modules 1&2	\$1,800,000,000	95	\$18,947
Module 3	\$110,000,000	143	\$13,404
Module 4	\$110,000,000	190	\$10,632
Module 5	\$110,000,000	238	\$8968
Module 6	\$110,000,000	285	\$7860
Module 7	\$110,000,000	333	\$7068
Module 8	\$110,000,000	380	\$6474
Module 9	\$110,000,000	428	\$6012
Module 10	\$110,000,000	475	\$5642
Module 11	\$110,000,000	523	\$5340
Module 12	\$110,000,000	570	\$5088
Total	\$2,900,000,000	\$5088

Introduction

Society's growing concern about climate change, desire to move more people out of energy poverty, and aim to bring equity to technology deployment have created an opportunity for advanced reactors to contribute to the global clean energy transition. New,

innovative reactor designs have the potential to address problems across a multitude of facets: enabling faster and more resource efficient decarbonization by balancing out intermittent resources and/or providing heat for industrial processes (Jenkins et al., 2018); improving the economic case for deep decarbonization; offering versatile products for more markets, which can help bring more people out of energy poverty; and improving social license by integrating social justice considerations, mitigating concerns about used fuel, and simplifying safety systems.

The reactor designs that are being developed in a serious way in the early 2020s are not entirely new ideas as the basic concepts generally originated in the 1950s, but the potential for these designs to be broadly commercially deployed is new. The combination of societal need and technology development has created a fresh opportunity for the nuclear industry to help solve some of society's toughest challenges. This chapter examines the case for advanced reactors (ARs), summarizes the current state of development, and assesses how technical and social systems must be considered collectively for the best outcomes.

To realize the potential of these new reactors, however, there is a strong need for innovation across the technology space, within social frames, in organizational structures, and in cultivating leadership. The current state of the nuclear industry in the United States and Western Europe is mixed, with new builds mired in cost overruns and schedule delays (McMahon, 2018); and light water reactors (LWRs) are shutting down early in tough-competition markets, taking valuable clean energy off of the grid (<http://www.beyondnuclear.org/reactors-are-closing/>). It is also clear that the nuclear industry needs to think and act differently regarding equity of access and participation across boundaries of race, gender, and more (Turner et al., 2020). If the nuclear industry is serious about getting new outcomes, they must do things differently than they have in the past.

Fortunately, the industry can thoughtfully engage in developing new approaches and structures for nuclear energy deployment as the next decade provides a unique opportunity to execute. New companies have formed and are growing, new leaders are emerging, the regulatory environment is being defined for non-LWRs, the US government is providing funding in new and creative ways for ideas to move from the laboratory up the commercialization ladder, conversations around international engagement are changing, and new supply chains are being envisioned and the groundwork for them is being laid. All of this is of course a snapshot in time and some of it will change by the time you read this chapter.

There are many reactor designs to choose from, with different types using different technical approaches to resolve the challenges the designers think are most important. The answer to which design is best depends very much on the value judgment of what is most important, or which combination of things are most needed. Is it the best economics? Is it balancing renewables on the grid? Is it limiting and eliminating nuclear waste? Is it providing high-temperature heat? Each community and country must choose for themselves what they value since the answer is unlikely to be the same everywhere. This chapter endeavors to provide some framing for how these choices might be made.

The case for innovative new reactors—What problems could we solve?

Society is facing climate change, economic and racial disparity in access to energy and quality of life, and health impacts from air pollution. Nuclear energy is already helping to mitigate some of these problems as it is a major source of clean electricity globally and has the additional benefit of being a firm resource (Jenkins et al., 2018) ([https://www.iea.org/data-and-statistics?country=WORLD&fuel=Energy supply&indicator=Electricity generation by source](https://www.iea.org/data-and-statistics?country=WORLD&fuel=Energy%20supply&indicator=Electricity%20generation%20by%20source)). New reactor designs that are available today, termed Generation III+, have enhanced safety features compared to the existing Generation II and III reactors, but their construction costs and timelines have varied globally and not all electricity grids and markets need the 1 GWe-sized, baseload power plants that are Gen III+ (CleanTech Catalyst Ltd., 2018; Sah et al., 2018).

The combined need for clean, firm energy resources and the limitations of Gen II to III+ LWRs create the need for nuclear energy systems that can fill the gaps and improve upon specific challenges—though there is certainly still a strong need for the existing reactors everywhere and new Gen III+ plants in many parts of the world. Advanced reactors are poised to do just this, and the remainder of this section describes the existing barriers and how ARs may overcome them.

Market fit

Advanced reactors have the potential to improve the “buy-ability” of nuclear systems. The often-determining consideration for what electricity sources are constructed is economic, where the economics are set by overnight capital cost, construction time and timeline certainty, and cost of operations and maintenance (Rothwell, 2021). A second prerequisite for market fit is generating the amount of electricity needed for a particular market. In the United States, due to the fragmented electricity market spurred by deregulation, none but the largest utilities can currently afford to build nuclear energy projects. This is also true in many countries. Smaller reactors with factory fabrication and certain delivery dates could open up entirely new markets (Ingersoll, 2021). An important area for innovation is in reducing the cost and risk to build and operate new nuclear plants.

Overnight capital cost

Generation III+ plants are being built in several parts of the world at widely varying cost. In Asia and the Middle East, the costs are fairly reasonable and in some places are even competitive with other generation sources. In the United States and Western Europe, however, the costs are shockingly high, multiple times higher than the predicted project prices, and much higher than other generation choices. It is unlikely that new large LWRs will be built in many places because the costs are so high and so unpredictable.

An item that can exacerbate high and uncertain capital cost is a long and uncertain project timeline. Most nuclear projects are financed through loans. Riskier projects garner higher interest rates. Further, the longer the project takes, the more time before revenue is generated and the more interest is paid on the loan. Thus, when projects have high variability of cost compounded by a longer than planned schedule, finance costs can become significant. Increasing predictability of cost and timeline would reduce finance cost, and reducing time until revenue generation would have an additional benefit.

Advanced reactors are projected to cost slightly less to significantly less than Gen III+ reactors, depending on reactor type. The Energy Options Network (EON) worked with eight AR companies to do a rigorous cost analysis. EON used the plant cost accounting framework developed by the Generation IV International Forum (Stanculescu, 2021) as the basis for a cost model for n-th of a kind nuclear plants (Energy Options Network, 2017). This work found ARs could cost as much as \$5885/kW to as little as \$3782/kW (in 2016 \$). This range is significantly lower than what is being constructed currently in the United States and Western Europe and lower than what is projected by the US Energy Information Administration (EIA) for Gen III+ plants. It is noteworthy, however, that the projected lowest-cost reactors are still more expensive than projections for many other new generation forms and more expensive than the Gen III+ reactors being built in parts of Asia and the Middle East.

ARs aim to cut overnight costs using a few different approaches. Many are taking the approach of factory fabrication and design standardization, avoiding the redesign and bespoke work that drives up costs of projects now and increasing predictability of schedule and cost. Factory fabrication will allow for part standardization and to take advantage of new techniques like additive manufacturing for complex parts. Some are operating at lower or no coolant pressure, which means components can be thinner, lighter, and less expensive. Inherent safety features can lessen the complexity of design and number of components, and reduce the size and weight of the concrete installations needed. Smaller reactors simplify things. Overall, these designs are working very hard to reduce cost and construction schedule, and increase predictability.

Operations and maintenance costs

Once a reactor is constructed and operating, there are costs to keep that reactor running. Those costs include fuel, staff, supplies, periodic improvements, etc. We typically break the cost of electricity into levelized capital costs, which recoups the cost of construction and any capital improvements over time; variable operations and maintenance (O&M), which includes variable costs like fuel; and fixed O&M, which includes costs that don't change with electricity output, like staff salaries. The fixed costs are important as they must be paid whether electricity is being sold or not—where no sale means no income.

Existing nuclear reactors have very high fixed O&M compared to other generation sources, and this has become a major challenge in the United States. Ten nuclear reactors closed early between 2013 and April 2020 because the costs to operate them are too high (<http://www.beyondnuclear.org/reactors-are-closing/>). O&M costs for nuclear are more than 50% higher than the costs for hydro and fossil steam, and about three times the costs for natural gas (https://www.eia.gov/electricity/annual/html/epa_08_04.html). The EIA's projected O&M costs for new assets coming online after 2025 slates Gen III+ plants with the highest fixed O&M costs, with only geothermal and biomass having fixed costs that are nearly as high. This gives the concern that the financial challenges facing the current fleet will still be a concern for Gen III+ reactors.

What about the next generation of reactors? Since we have little or no operating experience with ARs, all O&M estimates are based on best-guess values largely based on what we know about operating large LWRs (Buongiorno et al., 2018; Energy Options Network, 2017). Some reactors have the potential to have competitive O&M costs, and others are currently projected to face the same challenges as existing reactors.

This is a key area where new technology could make a difference. Many industries are dramatically reducing O&M costs by using predictive maintenance, advanced control systems, and asset performance management. These ideas use modeling and simulation, real time data collected from the assets, and artificial intelligence to accurately determine the operational state of individual components, a whole plant, or a fleet of plants. This information can automate operations, optimize maintenance, and reduce staff—all of which can dramatically reduce cost and make reliability easier to attain. These types of technologies will be especially important for new reactors since we do not have decades of operating experience. Simpler plant designs and improvements in how we can design plants to be easy to defend may allow for significant reduction in security forces. With all of these ideas, some reactors designs may be able to have very low staffing numbers, and microreactors may be able to be fully autonomous for long periods of time (Slaybaugh et al., 2019).

Multiple products for multiple markets

The reactors available to purchase today generate approximately 1 GWe (1 Giga-watts of electricity), require a substantial water resource for cooling, and a specifically-trained workforce for construction and operation. It may seem obvious, but not all locations that need electricity need 1 GW of electricity in one large installation, have a lot of water available for cooling, or have the desire to build the workforce and infrastructure needed. One of the major benefits of ARs is that a variety of reactor sizes and types will be available and able to meet the needs of more locations.

Some places may need less than 1 GWe because of limitations of the grid for transmission of electricity or overall electrical needs. Natural gas plants average about 500 MWe, and the capacities of coal plants that might be retired range from ~50 to ~800 MWe. With these plant sizes, it may not be possible to replace fossil plants with nuclear plants if the nuclear plant is much bigger than the system it would be replacing. Another barrier is that some countries or some utilities cannot finance a large reactor. Being able to buy a nuclear power plant made of a number of small reactors sequentially installed would decrease the cost per unit installation such that a new system could be affordable.

The smallest AR may be as small as 1 MWe, with many intermediate increments: 10, 50, 300 MWe, etc. and may have other benefits in addition to size choice. Some new designs don't require water for cooling, which dramatically expands which locations are appropriate for installation. Many new reactors don't require refueling, a complex operation requiring a surge in highly-trained personnel, for 5 to 30 years. Others need very few operational staff and can be buried underground to make physical protection much simpler. The range and versatility of products allows communities to find an AR that works for them, should they choose to benefit from nuclear energy.

Nuclear energy is a firm resource that does not emit carbon, which will be essential for a decarbonized grid. The considerations about construction cost, operating cost, water use, operational complexity and workforce needs, and generation size are important ones. However, this remains to be proven and the onus is on the nuclear industry to ensure they execute the vision they created.

Grid integration and process heat

Electricity generation sources are not islands; they integrate with all the other sources on the electricity grid and interface with the grid itself because, in the end, the supply for electricity must meet the demand. Thus, choices about generation sources need to consider all of those factors collectively. Advanced reactors may make it easier and cheaper for us to meet demand reliably in a very low carbon economy.

To be able to meet the demand, it is helpful for supply to be predictable and controllable. However, society also has very strong goals around not emitting air-pollution. The intersection of these goals can be difficult because some low-carbon resources are intermittent, such as wind, solar, and hydropower without large reservoirs. That is, we can't control when the wind blows, the sun shines, or the rain comes down. These sources therefore vary over timescales of seconds to seasons.

Historically, balancing intermittent resources has not been too concerning because there were not many of them on the grid, but that is changing. To reach our emissions goals, however, we need more renewable, intermittent resources, and many states in the United States and countries around the world have been adding large quantities of intermittent resources to meet their carbon and air pollution goals. We expect this trend to continue and accelerate, so we will need good mechanisms to bring on more and more intermittent resources while reliably meeting demand.

We can balance some of this variability with good forecasting and controls combined with balancing or "fast-burst" resources such as batteries, simple cycle gas turbines (with carbon capture and sequestration (CCS)), demand response, or flexible demand (Ela et al., 2013). These balancing resources have a response time that matches the shortest variation time of intermittent renewable resources. Coal, combined cycle natural gas, and nuclear do not vary their output too quickly, so are not well poised to balance the quickest changes in variable resource output (Gonzalez-Salazar et al., 2018).

For the multi-hour to seasonal scale of variation, we need "firm" low-carbon resources that can be counted on. This is where nuclear, coal and natural gas with CCS, large hydro, geothermal, and biomass come in. We need these technologies to operate flexibly enough to balance out naturally-varying resources over longer time scales. To date, combined cycle natural gas has largely been used as the variable firm operational source to meet varying demand. Nuclear and coal are operated in a "baseload" frame: they run at constant power unless they need to be shut down for maintenance or refueling. If we are serious about our decarbonization goals, this will need to change because these baseload resources will need to become variable in a controlled fashion.

Existing LWRs can vary their electrical output to some extent. They can directly vary their electrical output using reactor power changes. There are physics limitations on how fast, how much, and how often this strategy can be employed though, even for plants that were built with the intention to "load follow" or vary their output (OECD, NEA, 2011). Larger, more rapid power changes can be achieved by temporarily directing the steam away from the generator, but this is not a desirable solution as it is wasting energy (Jones, 2011).

Advanced nuclear reactors offer a few pathways to higher levels of variability that may enable really large deployments of intermittent resources. This is an essential feature of advanced reactors. Some reactor designs are intended to directly vary their electrical output. Other designs are intended to run constantly at full power and have a thermal storage system attached that can vary electrical output. When demand is low, heat will be directed to the storage system rather than the electrical generator. When demand is high, the stored heat can be used in conjunction with the reactor to produce electricity. Finally, many ARs are designed to operate at higher temperatures. They can divert the produced heat directly for industrial processes, or to generate co-products like hydrogen or synthetic fuels in a manner similar to the thermal storage approach. Which approach will be best will depend on the specific market needs, the reactor technology, and many implementation details that will dictate cost tradeoffs (Lucid Catalyst, 2020; Clean Energy Ministerial, 2020). The main point is that there are many pathways to flexible nuclear reactors that can match the needs of a very low carbon grid.

To fully decarbonize the global economy, we need to focus on more than electricity alone since greenhouse gas emissions come from many sectors that cannot be electrified (<https://www.epa.gov/ghgemissions/global-greenhouse-gas-emissions-data>). The EPA notes that the 21% of global emissions associated with industry "primarily involve fossil fuels burned on site at facilities for energy." The heat needed for industrial processes needs to be replaced by non-emitting sources.

The temperatures needed for industrial process heat range from 50 °C to 2200 °C. A combination of nuclear with solar thermal and geothermal energy in the locations where those options are viable has a strong potential to fill some of these needs, with technology match depending on exact temperature needed, heat transfer modes, quality of heat, etc. Light water reactors produce steam a little under 300 °C; concentrated solar plants typically operate around 400 °C, though this range is expanding; and geothermal plants typically operate at lower temperatures but vary by installation detail (<https://www.eia.gov/energyexplained/solar/solar-thermal-power-plants.php>). As detailed below, advanced nuclear plants are slated to reach up to 1000 °C, so they could provide heat to a large number of applications (McMillan et al., 2016).

Beyond industrial heat, nuclear reactors are particularly well suited for other industrial applications like hydrogen production, desalination, and district heating. The Department of Energy (DOE) has a program that is researching flexible use of small modular light water reactor modules, whether for hydrogen generation, process heat, or load following. Such a program will help prove out the details of some of these ideas so industry and communities will be able to have the details they need for decision making.

In many countries, intermittent electricity resources are becoming more prevalent and to meet our decarbonization goals this trend needs to increase over time. Further, sectors like heavy industry need to be decarbonized. Many studies show that the availability of flexible and high-temperature reactors can help decarbonize the global economy faster and at lower cost because they can balance renewables and provide heat (Jenkins et al., 2018; Lucid Catalyst, 2020; <https://inl.gov/article/advanced-reactors/>).

Social license to operate

While existing nuclear power plants typically have strong public support, there has long been ardent opposition to nuclear facilities across all aspects of the technology, particularly mining and milling of uranium as well as waste disposal sites. Certain characteristics of advanced reactor concepts could improve social license to operate—the ongoing acceptance or approval of a project from the relevant stakeholders—as detailed below, but other challenges cannot be mitigated with technology alone and will need commensurate public policy to ensure positive stakeholder experiences with technology adoption. Section “What’s needed in tandem with technological innovation to improve outcomes?” details these ongoing challenges.

Improving the social license for nuclear energy might start with expanding the market to new customers like smaller municipal utilities, rural electric cooperatives, off-grid communities, and a larger range of industrial users. This would allow for gaining social acceptance by providing local benefits such as zero-emissions electricity generation and high-paying jobs. The ability to have local control over a power plant may facilitate stronger social license.

Some of the greatest environmental justice issues related to nuclear energy concern the fuel cycle. Significant work still needs to be done to address legacy pollution issues from nuclear weapons production and testing as well as uranium mining and to make progress on nuclear waste disposal. Some AR designs are looking to address fuel cycle concerns by recycling used fuel, which will reduce mining needs and simplify disposal, resolving some of the largest objections to the nuclear industry. While fuels vary widely across reactor technologies, some have the potential to use fuel more efficiently and even burn nuclear waste as fuel. These characteristics could reduce the need for fresh fuel mining, reduce the volume of spent fuel produced, and extend the time between reactor refueling (meaning less transport and handling of fuel in local communities).

The simple, “walkaway” safe nature of many advanced reactors also has the potential to strengthen social license. Power plants that rely on inherent and passive safety features may have an easier time gaining the trust of potential host communities than those designs with complex engineered safety systems. The promise of no off-site consequences in the event of an accident, along with a reduced need for back-up power and emergency cooling reserves, may also reduce dread. Yet these safety attributes will need to be proven to host communities before they provide meaningful reassurance.

Although not intrinsic to any advanced reactor concept, the makeup and structure of the developers has also changed and may improve social license. Originally, nuclear technologies came out of the military and so did much of the workforce. While many advanced reactor concepts were also born from government programs, their modern commercial development is coming from new companies that look very different: younger, more diverse, more focused on equity. Many of these reactor companies were spun out of university programs, raising a mix of private and government investment, and their workers are driven by concern for climate change and energy poverty. Such changes in the fabric of technology developers may not change the public’s minds about nuclear technology on its own, but these new companies may also come with different models for how community engagement, government interaction, and how they do business more generally.

Advanced reactors are quite different from existing reactor designs. These technical differences mean they may be more economic, fit into more markets, help us achieve deep decarbonization faster and in hard sectors, and improve social license. Changes to who is building and designing these reactors may also improve social license. In all cases, we must execute the vision thoughtfully and diligently for these possibilities to be realized.

Overview of new innovative reactors under development

There are many AR designs currently in development, each with a different combination of materials, sizes, and operating regimes, that may be better suited to different purposes and markets. Commensurately, there are many companies, new and old, working to develop what they think is the best reactor. No two designs are the same, though there are some general categories. The major variables that people select from to comprise their reactor design include the following, noting that this list is likely not exhaustive (Milko et al., 2018; Freed et al., 2015):

- *Electrical output:* microreactors may be 1–10 MWe, small modular reactors are often 50–300 MWe, and large reactors are on the order of 1 GWe.
- *Power conversion system:* most ARs plan to use a steam Rankine cycle, but some are planning for CO₂ Brayton cycles.
- *Heat transfer medium:* light (regular) water, sodium, gas (usually He), lead (or lead-bismuth alloy), molten salt (fluorides, chlorides, or nitrides), heat pipes, supercritical water, organics, and supercritical CO₂ are all options.

- *Fission operating regime*: fission reactors use neutrons to split unstable isotopes. The energy of the neutron causing fission can be near the energy they are born, “fast” (on the order of MeV), or in thermal equilibrium with the system, “thermal” (on the order of meV). Whether a neutron is fast or thermal determines which isotopes it can fission.
- *Fuel form*: oxides, nitrides, metal, tri-structural isotropic (TRISO), molten salt, silicon carbide clad, metal clad, are all options.
- *Fuel enrichment*: some reactors will operate with the enrichment level currently used, 3–5 wt% U-235, while others will use nearly 20 wt%, and many somewhere in between.
- *Operating Temperature*: LWRs have a core outlet temperature of $\sim 285\text{--}330^\circ\text{C}$, while many non-LWRs will operate around 650°C or even 1000°C .
- *Operating Pressure*: some reactors operate at atmospheric pressure, many operate in the range of 7–17 MPa, while the highest pressure systems are 25 MPa.

These different options are combined in different ways. **Table 1** provides a non-exhaustive list of some key features of different reactor categories. The World Nuclear Association provides a good overview of many different advanced reactor designs, details, projects, and collaborations (<https://www.world-nuclear.org/information-library/nuclear-fuel-cycle/nuclear-power-reactors/advanced-nuclear-power-reactors.aspx>).

With all of these options, how does a community think about what to choose? Each reactor type fills a particular market purpose. However, each also has drawbacks or challenges. Which reactor is the best choice will depend on the needs of a particular community, market, or country. Some brief points on several reactor types being pursued are given below, followed by a more in-depth look at two particular reactor designs. Note that the following discussion does not cover all reactor designs or design variations.

Small modular LWRs use the same basic technology as large LWRs, but their smaller size could give them smaller financial risks and simplify safety systems. It is possible to manufacture modules of the reactor in a factory and ship them to site, which should provide an economic benefit via standardization and economy of mass production (Ingersoll, 2021). Each individual module would be lower total cost (even if the cost per MW is higher), which should make it easier to finance each module. The smaller size makes it easier to match load if there is a collection of modules as some modules can be turned off or on while others are ramped a little bit. Finally, the smaller core size gives safety benefits just because each reactor has less material, so the maximum accident is less impactful. The main drawback compared to large LWRs is that the smaller size reduces the economy of scale, which may not compensate for the economy of numbers, ease of financing, and smaller maximum accident impact.

The main benefits of gas-cooled reactors are high temperatures that can be used for industrial processes and extreme safety characteristics (the VHTR and GCR have similar characteristics). Because they use a gas coolant and TRISO fuel (Helmreich, 2021; Gerczak, 2021) the maximum accident the plant could experience is limited, with no scenarios causing fuel melt. GCRs have been built and operated commercially, so we have more operating experience and data with them than many with other AR types. The graphite moderator used in this reactor core causes the power density to be low, so GCRs tend to have cost challenges because they are large compared to how much power they generate. A second drawback is that the TRISO fuel form cannot be recycled and GCRs are not set up to consume used fuel.

The main benefits of SFRs (Heidet, 2021) are that the fast spectrum can be used to increase uranium utilization by two-orders of magnitude as well as to consume nuclear waste generated in thermal reactors. These reactors have moderately-high temperatures that could be used for industrial purposes. SFRs have very strong neutronic safety features and benefit from operating at atmospheric pressure, but that must be balanced against the fact that sodium is highly pyrophoric which greatly complicates operations. An additional challenge is a relatively high radiation damage rate to structural materials. There is some experience in operating SFRs primarily in Russia and France. The United States has operated a number of experimental SFRs.

The LFR has similar benefits to the SFR (Alembreti, 2021). The temperature and pressure regimes are similar, and LFRs can also be used to efficiently utilize uranium and to consume waste. LFRs also have strong safety features. A main reason people are

Table 1 Physical properties of several advanced reactor categories.

Reactor	Neutron spectrum	Coolant	Core outlet temperature ($^\circ\text{C}$)	Pressure (MPa)	Size (MWe)
Current LWRs	Thermal	Water	285–330	15.5 (PWR) 7 (BWR)	1000–1200
Very-high-temperature reactor (VHTR)	Thermal	Helium	900–1000	7–17	250–300
Sodium-cooled fast reactor (SFR)	Fast	Sodium	500–550	~ 0.1 (1 atm)	50–150 300–1500 600–1500
Supercritical-water-cooled reactor (SCWR)	Thermal/fast	Water	510–625	25	300–700 1000–1500
Gas-cooled reactor (GCR)	Thermal	Helium	850	9	1200
Lead-cooled fast reactor (LFR)	Fast	Lead	480–570	~ 0.1 (1 atm)	20–180 300–1200 600–1000
Molten salt reactor (MSR)	Thermal/fast	Salts (F, Cl, or N based)	700–800	< 5	1000
Microreactor	Thermal/fast	Heat pipes/helium			1–10

interested in lead is that it removes the pyrophoric consideration when compared with SFRs. However, the lead introduces major corrosion challenges that have not yet been reliably resolved, can introduce issues of freezing, and the production of significant amounts of polonium introduces a radiological hazard for operators. Russia has experience operating LFRs.

MSRs have more variations than the other reactor types (Ignatiev, 2021). The main benefits across all MSRs are potential to provide process heat and to load follow either directly or with secondary power conversion systems—the secondary salt coolants are good candidates for using in thermal storage; and very strong safety features—they cannot have melt-down accidents. Some designs have liquid fuel and some have solid fuel. Some are fast spectrum and could therefore burn waste. Different designs use different types of salt. For many MSRs there are challenges with corrosion and large operational radiation environments such that all maintenance will need to be conducted by robots. We have built one experimental MSR.

Microreactors have a whole chapter devoted to them (Lovering, 2021). Briefly, their main benefits are ability to fit into totally different markets, load following, and extreme safety. The different microreactor designs are quite different from one another, but their key characteristics are similar. For many microreactors the designs focus on simplicity of design and construction, which should ease deployment. The major question is whether the cost/MWe can be low enough and whether they will be able to achieve the very low staffing numbers they are targeting.

In this article we will describe two advanced reactor concepts that have engaged with the Nuclear Regulatory Commission (NRC) for review and approval in different capacities. These are indicative of the types of plants being considered in the future employing some of the attributes mentioned earlier.

NuScale: Small modular PWR

NuScale has designed a small modular Pressurized Water Reactor (PWR), and this technology may be one of the first new reactors deployed. The NuScale design uses the basic technology of PWRs: regular water coolant, low-enriched uranium (LEU) dioxide fuel, zirconium-alloy cladding, and operates at similar temperatures and pressures. However, the first NuScale reactor has many design innovations (<https://www.nuscalepower.com/technology>). For example, it uses the so-called integrated design in which all the primary reactor coolant components are within the pressure vessel and the primary coolant removes the fission energy by natural circulation. This design approach eliminates the primary pumps, valves, and external piping and vessels, thus increasing the plant's robustness and also reducing construction and maintenance costs. The reactor vessel is located below grade in a pool of water. The water serves multiple purposes, including passive containment cooling and decay heat removal. That is, the pool provides a heat sink with a capacity to absorb all the decay heat produced by a fully mature core for greater than 30 days.

Each unit is 60 MWe instead of the 1000 MWe of present day commercial reactors. The relatively small power per unit has important safety advantages (Ingersoll, 2021) and enables modular construction. Each NuScale reactor vessel is 2.7 m in diameter and 20 m tall, weighing 590 metric tons. The reactor module would be pre-fabricated, delivered by railcar, barge, or special trucks, and assembled on-site. The NuScale power plant construction time is expected to be much smaller than that of conventional LWRs.

NuScale is betting that the similarities with existing technology means they will be able to leverage a lot of existing supply chains and they will not need to get materials or fuel newly qualified, which can take a lot of time and money. Similarly, the knowledge base to keep nuclear materials safe from proliferation should apply to NuScale's design.

Historically, nuclear power plant construction has been site-customized, with everything built on site, and many items redesigned and customized for a specific plant installation. In the United States and Western Europe, this approach has been demonstrated to be very slow and expensive. NuScale's design will avoid this pitfall by having all the plant components manufactured at a factory and shipped to site for assembly—though the civil works will still be site-specific, which may prove to be a time and cost burden (<https://www.nuscalepower.com/technology/fabrication-and-assembly>). With a large number of plant orders, this factory approach should lower costs and improve learning and quality control.

As discussed, load following is likely to become increasingly important in a low-carbon electricity grid. The plan to install multiple units at one site gives granularity to power output. A "full pack" is twelve 60 MWe units, creating a 720 MWe plant. The individual modules can come on or offline in a ~1 day timeframe. For faster power changes, individual units can be ramped up or down and for very fast changes they can execute a steam bypass strategy. It's unclear whether these approaches will be economic—that will ultimately depend on the market and the operational costs. Instead of power change, heat could be diverted for industrial processes. How well this works and how financially viable this approach might be will be studied by the DOE.

Because the modules are independent they can be purchased individually and in series, which could make financing easier. The cost of an individual module will be much less than 12 at one time, so the total financial risk is lower which could enable better loan rates. The combination of lower capital outlays and better loan terms means smaller entities could more easily buy a reactor. Additional modules can be added after the first one or several are already operating and generating revenue, again reducing financial risk and making these easier to buy.

NuScale is betting that the similarities with existing LWR technology means their design will be easier to license and regulate because the NRC is familiar with LWRs. There were still major differences to be addressed, like using one control room for up to 12 modules and shrinking the emergency planning zone (EPZ) to the site boundary rather than 10 miles. Having one operating room will improve operational efficiency and reduce fixed O&M. The small unit size means natural convection can be used in emergencies to remove decay heat and the plants are very robust, so emergencies would never go beyond the site boundary. NuScale submitted their design certification application in January 2017 and the Final Safety Evaluation Report was completed and approved in September of 2020 (<https://www.nrc.gov/reactors/new-reactors/smr/nuscale/review-schedule.html>).

Not only is NuScale's the first new type of reactor to get a design certification, in principle it already has a customer. The Utah Associated Municipal Power Systems (UAMPS) is planning to site 12 modules at Idaho National Lab. DOE is providing matching funds for site preparation and the combined operating license application. At first the plan was for UAMPS to vote on the final notice to proceed for construction in 2023, with plans for the first NuScale plant to achieve operation by 2026, but by August of 2020 that plan was delayed to a 2030 operation date and made contingent upon DOE providing \$1.4 B to offset increasing costs (Cho, 2020; <https://www.nuscalepower.com/newsletter/nucleus-spring-2019/powering-the-next-generation-of-nuclear>). The delay is based on the projected power needs of the UAMPS communities, not because of changes in NuScale's trajectory. NuScale is doing customer engagement and communications in a more modern and forward thinking way, which may help them work through the timeline and cost issues with UAMPS.

X-energy: High-temperature gas reactor

X-energy is designing the Xe-100, a small, modular, helium-cooled, pebble bed reactor that is to generate 80 MWe, intended to be sited with up to 4 units for 320 MWe installations (<https://x-energy.com/reactors/xs-100>). They will use TRISO fuel that is enriched above 5% but below 20% U-235, called high-assay low-enriched uranium (HALEU), with a graphite moderator. The Xe-100 uses online refueling, has a 750 °C He outlet temperature, uses a steam power conversion cycle, and focuses on using approved materials as much as possible. They, too, will have an EPZ that does not extend beyond their site boundary. X-energy is counting on safety, modularity, high-temperatures, and fuels and materials that the industry has some experience with for their technology to be adopted. They are focused on designing a plant with strong focus on economics and deployment—something that can be factory manufactured and use existing knowledge, supply chains, and infrastructure as much as possible. They are also working on sophisticated operations and maintenance strategies for fast licensing and low-cost operations (https://arpa-e.energy.gov/sites/default/files/documents/files/GEMINA_Project_Descriptions_FINAL.pdf).

One of the potential benefits of gas reactors for a future grid is the high temperature heat. The heat in the form of He or steam (565 °C) enables generating electricity at a higher efficiency than in LWRs and could be directly used for industrial purposes. There is the option to add a secondary power conversion system that could be used for load following, which might be a good choice for this plant since the higher temperatures improve the efficiency compared to lower-temperature systems. The Xe-100 can refuel without shutting down, which eliminates downtime for refueling and should be an economic advantage.

While a more efficient power conversion could be attained if X-energy used the helium directly to drive a gas-turbine, by choosing a steam cycle they can use existing supply chains and rely on technologies the industry knows and trusts. X-energy has selected an ASME standards-compliant core barrel, steam generator, and reactor vessel, making it easier to use existing supply chains and fit into existing regulatory frameworks. This should reduce risk and time to deployment. X-energy has engaged in pre-licensing activities with the NRC, but has not submitted a license application (<https://www.nrc.gov/reactors/new-reactors/advanced/xs-100.html>). The Xe-100's will also keep their design small and modular so they can take advantage of the benefits of factory fabrication.

There is not a supply chain for HALEU, but the DOE is working to change that. X-energy has TRISO fuel manufacturing capability, so once a HALEU supply is secured they will have a secure fuel supply chain. There are several key benefits from using TRISO. There is significant experience with this fuel form, which means it is likely easier to qualify than many other new fuel forms. It is extremely safe, which creates the foundation of the very strong safety of gas reactors. However, the TRISO fuel form is comparatively bulky, and it is nearly impossible to reprocess it. This may be beneficial from a non-proliferation perspective and detrimental from the perspective of closing the fuel cycle. It remains to be seen how cost effective HALEU TRISO is since the low fuel density is the main driver of the low power density that challenges gas reactors economically.

Like NuScale, the Xe-100 will not need an EPZ. Gas reactors have low power density, high thermal inertia, and very robust fuel. These very strong safety features mean the reactor cannot melt down. Having a low EPZ means the reactor can be sited in more locations more easily, reduces emergency planning burden, and reduces staff required to manage accident response. Mostly, though, not ever needing to evacuate a community is strongly beneficial to gaining social license to operate.

Overall, X-energy is relying on the combination of these features to give them a competitive reactor: modular manufacturing, small size, high-temperature heat source, very long up times (high capacity factor), many proven components, and extreme safety. The design has yet to be certified, and a gas reactor is quite different from a light water reactor. There are questions about fuel supply and cost, and the overall economics remain to be proven.

A historic challenge that must be avoided for whatever reactor design moves forward is that the nuclear sector needs to be accurate in its time and cost estimates. That is, not only does the sector need to develop technologies that can be economically viable and adhere to reasonable timelines, they also need to be better at the projections they make. For example, In 2008 NuScale thought perhaps they could have a reactor online by 2015. They did not even submit a license application until 2017. While there were extenuating circumstances that caused this delay, the pattern has remained consistent across the sector in the United States: wildly inaccurate timelines and costs. These issues do not demonstrate that the industry is investible or a good partner. For nuclear energy to have a future, it has to be able to keep the promises that it makes.

What's needed in tandem with technological innovation to improve outcomes?

It is clear that advanced reactors offer many unique attributes that have the potential to alleviate many of the challenges with existing nuclear energy, including public opposition. Yet the success of these designs is not guaranteed based upon improved engineering. There is a host of complementary policies that need to be developed to facilitate equitable adoption of these novel technologies.

Along with technological innovation, there is an opportunity now to develop novel organizational structures, modern infrastructure and regulatory regimes, and new business models that will facilitate equitable adoption of advanced nuclear designs. Below is a summary of the areas that still require parallel innovations.

Fuel cycle

The United States has struggled to establish a holistic, sustainable, and closed fuel cycle that accounts for mining, uranium supply chains, fuel fabrication, waste management, and legacy nuclear materials—which includes clean up from the nuclear weapons program still ongoing at more than a dozen sites across the country (<https://www.energy.gov/em/mission/cleanup-sites>)—and the respective impact of these activities on communities. Environmental contamination issues across the fuel cycle have resulted in legitimate concerns about the viability and safety of nuclear energy. As a result, many states have explicit policies that ban the construction of new nuclear facilities until a nuclear waste solution is available (<https://www.ncsl.org/research/environment-and-natural-resources/states-restrictions-on-new-nuclear-power-facility.aspx>). One way forward could be to develop a national strategy aimed at addressing and expediting ongoing clean-up efforts and redesigning the US fuel cycle for a new generation of advanced reactors. The introduction of new fuel forms invites the possibility of creating a new, more sustainable fuel cycle that considers where and how materials are sourced and manufactured, and where those materials ultimately go after their use.

Workforce

The new suite of advanced reactor designs will look quite different from the LWRs we have now, and those differences offer an opportunity to rethink how the industry approaches problems as well as what problems need to be addressed. The industry needs to foster a new generation of workers that is creative and adaptable, ready to meet the complete set of complex challenges associated with nuclear energy, not just the technical subset. The workforce should reflect the diversity of the communities that will be hosting these advanced reactor projects. Going beyond engineering, this new workforce will need to be broader and more interdisciplinary; reactor designers, management, and anyone public-facing will need to understand the complex challenges of social license, environmental justice, and an evolving regulatory process. For example, employees at vendor companies who are working in community engagement and siting should have a broader background that could include but is not limited to: anthropology, geography, history, politics, communications, psychology, sociology, and science and technology studies. Management should work to integrate teams with both technical and non-technical backgrounds to address emerging challenges.

Regulation

Recent legislation signed into law in the United States, like the Nuclear Energy Innovation and Modernization Act (NEIMA), have made incremental progress on improving the regulatory process for advanced reactors. Specifically, NEIMA instituted a more equitable and transparent fee structure for applicants and directed the NRC to develop a technology-inclusive licensing framework (<https://www.nei.org/news/2019/president-signs-bill-to-modernize-nuclear>). Yet much more work needs to be done to streamline the licensing process for future owners and operators of advanced reactor projects, especially for smaller utilities and municipal customers. Some modular reactor developers are envisioning a deployment model that is closer to “plug-and-play” than in existing nuclear power plants, with much less on-site construction. To facilitate this adoption model, there will need to be parallel innovations to create licensing templates for potential customers to standardize and streamline the process. Without such improvements, the challenges of the licensing process will continue to privilege the largest of electric utilities.

Siting

Traditionally, the siting of nuclear power plants has followed a simple model: announce, defend, build. Considered a Locally Unwanted Land Use (LULU), strategies to site new large LWRs in the United States typically involve the expansion of existing nuclear facilities in rural and suburban areas rather than looking to build projects in totally new locations (<https://onlinelibrary.wiley.com/doi/abs/10.1111/j.1539-6924.2009.01262.x>). However, advanced reactors have the potential to dramatically expand feasible siting areas, including: to both geographically isolated and urban domains; as direct replacements for coal and natural gas facilities; and as co-located with industry to provide high temperature steam, to be used for hydrogen production, desalination, or other co-products. All of these new adoption scenarios point to the limits of new nuclear plant siting at existing facilities and raise critical questions about the viability of traditional siting approaches going forward. New methods for identifying and working with host communities will likely be warranted and should take a bottom-up rather than top-down approach. Consideration must be given to how nuclear energy and nuclear fuel cycle facilities impact communities, and consent-based approaches should be developed to ensure those who are exposed to risks accrue commensurate benefits and that the benefits match with community needs.

Financing

New nuclear technologies may be smaller and cheaper to build overall, but financing such projects could still put them out of reach for all but the largest utilities. There are over 3000 electric utilities in the United States, and most are too small to carry the large debt

required for even a small nuclear power plant. Therefore, to make nuclear energy a viable option for these utilities, there will need to be new financing models appropriate for the innovative reactor designs. Public-private partnerships will be critical for the first handful of demonstration projects, but beyond that there will be a need for continued access to financing to allow a more diverse set of utilities to access these technologies. Loan guarantees for small utilities could help de-risk investment, along with continued production tax credits. Further support could come through agencies like the Rural Electrification Administration or state governments, especially those that have aggressive decarbonization targets.

Summary

Public perception about nuclear energy is mixed, with some people being very strongly against it and others being open to it or in favor of using it. The large challenges society is facing has caused many people to reconsider nuclear energy because of the technology's benefits. Advanced reactors provide an opportunity to improve public acceptance even more. Innovation in how nuclear plants are designed, built, and operated is needed. Innovations in design and construction are needed to reduce the cost of building and operating the plants to make them economically desirable. New markets beyond simply electricity generation are needed with designs that enable multiple applications such as process heat, desalinization, district heating, hydrogen production, and other industrial applications. To enable these applications, innovations are needed in safety improvements allowing for such collocation. Since many countries and companies cannot afford to build large power stations, small modular and right-sized reactors are needed to make them affordable. In addition to the technological innovations that are needed, innovations in licensing, financing, and community engagement from the local level to the federal level are needed.

Advanced reactors offer the possibility of making nuclear energy easier to use as a tool to fight climate change, reduce air pollution, and help electrify developing economies. These technologies offer real technical benefits to complement what large LWRs can offer. Moreover, ARs offer an opportunity to do things differently. Because the industry is inventing something new, there is an opportunity to implement new public engagement practices, new finance models, new business plans, etc. At present, there are over 50 innovative new designs at various stages of design and development all over the world. That gives us many chances to do it right.

Introduction

The acceptability of nuclear power from perspectives of the public, investors, and plant owners is a complex, multi-faceted issue that has seen repeated cycles throughout its 60-year history. These cycles have been influenced by many externalities such as regional or global economic strength, availability of energy alternatives, and political biases. However, the nuclear industry also contributes to the social, political, and economic swings of acceptance by virtue of its successes and failures of technology choices, business models, operational performance, and management acumen through all phases of design, engineering, construction, and operations.

The nuclear industry is on the verge of introducing a new paradigm in the delivery of nuclear power: small modular reactors (SMRs) (Ingersoll, 2016). The promise of SMRs is to improve on all aspects of design, engineering, construction and operation of commercial nuclear power plants in terms of enhanced safety and resilience, improved affordability and expanded utility. If fulfilled, these promises will have a significant impact on the acceptance of nuclear power to all stakeholder groups, including the general public, financial investors, and plant owners. Before reviewing these potential impacts in detail, a brief discussion of the nature of and motivations for SMRs is provided.

Background

The commercial use of nuclear power began in 1957 with the 60 MWe Shippingport reactor. Less than 15 years later, most new commercial plants built in the U.S. had capacities nearly 20 times larger, a trend that continues today world-wide. Fig. 1 demonstrates this rapid expansion of nuclear plant unit size. Currently, most new plant designs available on the world market range from 1100 to 1600 MWe, including several designs from France, Japan, the Republic of Korea, Russia and the United States. During the past few years, a number of reactor designers have turned to developing a new generation of commercial nuclear power plants with much smaller unit capacities. Commonly designated as “small modular reactors (SMRs),” they are generally characterized by having an electrical output of less than 300 MWe, are substantially fabricated in a factory and transported to a site for installation into a fixed building structure, and operated in combination with one or more identical reactor modules. Currently, there are over

^aRetired.

Fig. 1 Electrical output of commercial nuclear power plants build in the U.S. as a function of their initial date of operation (EIA, 2008).

50 SMR designs being commercially developed world-wide motivated by three key drivers: enhanced safety, reduced financial risk, and increased flexibility in deployment and use.

It is important to note that an SMR does not necessarily represent a new reactor technology, although it may. The reactor technology used in a specific design is largely driven by the intended use of the nuclear plant, such as electricity generation, process heat production, or fuel and waste management. Reactor technology is typically categorized by the type of coolant used to remove heat from the reactor core, and includes: water (H_2O or D_2O), gas (helium or carbon dioxide), liquid metal (sodium, lead, or lead-bismuth), and molten salt (fluoride or chloride). Of the nominally 446 commercial nuclear plants operating world-wide, 430 are water-cooled, 14 are gas-cooled, and 2 are sodium-cooled (Nuclear News, 2018).

Based on power level alone, an SMR may be a down-sized replica of a large plant design. For example, 29 of the 446 operating nuclear plants are small versions of larger plants, i.e. they use the same design and technology as large plants but have a power output less than 300 MWe. However, many new SMR designs use either dramatically different engineering principles to simplify the design or advanced technology, or both. They differ from large plants in the physical scale of the components, the relative placement of the components, and the multiplicity of the nuclear systems. In most cases, these SMRs are “deliberately small,” i.e. they cannot be reasonably scaled to larger sizes (Ingersoll, 2009).

The essence of the new SMR paradigm is to significantly change the fundamental philosophy of nuclear plant design and the approach to deploying nuclear power. The intent is to bring to the nuclear industry the kind of modularity that has already found success in most other energy generating technologies (coal, natural gas, wind, and solar) and to meet the needs of an expanded set of potential customers. With modularity comes the opportunity for standardization, scalability, and adaptability due to smaller component sizes and multiplicity of modules. Additionally, the reduced size of the individual nuclear units can provide enhanced safety (robustness) to the design, thus reducing hazard risk to the public and reducing financial risk to the investors and owners. These motivations and justifications are detailed in the sections below.

Motivations for SMRs

Most succinctly, the current global interest to design, license and deploy new SMRs is motivated by their promise of enhanced safety (resilience), affordability, and flexibility. The potential for smaller reactors to enhance plant safety/resilience beyond existing large plants comes from the application of different design principles that take advantage of system scale and natural phenomena. As an example, some SMR designs use gravity-driven natural circulation of the reactor coolant during normal operation, thus eliminating the possibility of a pump failure event and reducing or eliminating the need for emergency power during a station blackout event. Removal of the residual decay heat in a reactor core is made easier since the smaller reactor core produces less heat than a large core. Similarly, the inventory of radionuclides produced by the fission process in the fuel is less for small cores since the total quantity of radionuclides is roughly proportional to the power level. Some SMRs have module power levels less than 5% of a large reactor and

therefore will have less than $1/20^{\text{th}}$ of the potential for radionuclide release during a severe accident, even accounting for common-cause failures.

Affordability of SMRs comes mainly from having a lower purchase price. Values of \$6-10B have been cited for recent purchases of large nuclear plants. This huge price tag, and the financing challenge it creates, presents an insurmountable barrier for all but the largest utilities. SMRs offer the potential for improved affordability due to: (1) a lower total plant cost, and (2) the ability to add new generating capacity incrementally. Estimates of initial plant cost range from \$1-3B for SMR plants with total output of 200–500 MWe. Also, cash flow or capital-at-risk is much different for a multi-unit SMR plant than for a single unit large plant. The owner has the flexibility to stagger the construction or installation of the modular units, allowing the first unit to generate revenue earlier. The lower financing cost resulting from the reduced debt profile and the ability of the owner to better match their demand growth profile further reduces the total life-cycle cost of the plant.

Regarding operational flexibility, SMRs allow the owner to install incremental capacity at a rate that more closely matches demand growth. Additionally, the smaller generating capacity provides for better grid stability, especially in small-grid regions, since the unexpected loss of the power source creates a smaller perturbation on the grid. Finally, several plant features allow greater flexibility in plant siting, such as reduced water usage due to the smaller amount of rejected heat and simplified emergency preparedness due to reduced risk of radiation release. In the following sections, these motivations are explored in more depth and their potential impacts on acceptance by the public, investors and plant owners are reviewed.

Safety and public acceptance

The three most significant concerns commonly cited by the general public regarding nuclear power are: safety, nuclear waste, and nuclear proliferation. As mentioned above, SMRs are simply a different design approach than used for large reactors and they span the full gamut of reactor technologies. As such, they do not offer any particular advantage or disadvantage regarding nuclear waste and nuclear proliferation, which is primarily impacted by the choice of reactor technology. Therefore, these issues and their impact on public acceptance of nuclear power are deferred to other sections of this encyclopedia, specifically (Kadak, 2021) for waste and (Cheng, 2020) for proliferation. This leaves only the concern regarding nuclear plant safety to be addressed in this chapter, for which SMRs can have a dramatic impact.

The safety of nuclear plants in the U.S. initially crept into the national dialog in the early 1970s, due in part to an industry-led study to evaluate the statistical probability of reactor accidents. Anti-nuclear groups were quick to interpret the study as casting doubt on the safety of nuclear power and have been driving the public dialog in that direction ever since. The nuclear industry perpetuates this perception by being defensive about nuclear plant safety despite all evidence to the contrary. In reality, nuclear plants are incredibly safe. By any metric, the nuclear industry has one of the best records among all industries for protection of the workforce and the general public.

In a 2007 book, *The Geopolitics of Energy*, several common myths of nuclear power were discussed, including safety (Wright and Conca, 2007). The data in Table 1 are derived from the assessment of US fatalities in the period 2001–2006 and show the average annual number of deaths in the U.S. resulting from the listed activities. The leading cause of death was “iatrogenic causes,” which result from unexpected and unexplained outcomes of medical procedures. It was not surprising that smoking, alcohol and automobile accidents are high on the list—most people would expect that ranking. The fact that nuclear power is at the bottom of the list is likely a big surprise to many people. Operational injuries follow a similar pattern with the nuclear industry showing the lowest rate of injuries—even less than banking.

Despite the exceptional safety record of the nuclear industry, which has been consistently demonstrated over multiple decades of world-wide experience, many people, including industry advocates, persist with casting doubt on the safety of nuclear power. A key to improving public acceptance of nuclear power may rest with a clarification of terminology, specifically, distinguishing between *safety* and *resilience*.

Table 1 Average annual US fatalities for the period 2001–2006.

<i>Activity</i>	<i>Number of deaths</i>
iatrogenic causes	190,000
Smoking	152,000
Alcohol	100,000
Automobile accidents	50,000
Firearms	31,000
Coal use	6,000
Construction	1,000
Hunting	800
Police work	160
Nuclear power use	0

Safety and resilience

Plant *safety* is not at the discretion of the designer; it is an expectation set by the regulator. The designer is obliged to develop a design that meets those expectations in a convincing and substantiated manner. Safety standards established by the regulator are focused on reasonable assurance of adequate protection of the workforce and the public. The often cited concern for nuclear safety is not as much about its actual safety but rather a perception of its risk, which has both a technical basis and an element of emotion. For example, a person may be too afraid to board a commercial airliner but would not hesitate to jump into the family car—a much riskier proposition.

The US Nuclear Regulatory Commission (NRC) sets an extremely high bar on its established safety standards and is frequently referred to as the “gold standard” for nuclear regulation world-wide (Rempe, 2021). All reactor designs that have been certified by the NRC meet these exacting standards. The trend in new plant designs, large and small, is to meet the NRC safety standards in more assured ways, principally by making use of fundamental laws of nature whenever possible rather than relying on engineered systems that require operator action and a sustained source of electrical power to function. In doing so, the plant naturally becomes more resilient against unanticipated upsets.

All existing plants have been properly licensed and therefore are considered safe according to NRC standards. To further improve the designs, it may be instructive to think of designing beyond safety. This requires introducing new terminology that is a superset of *safety*, which is defined in the Webster New World Dictionary (Guralnik and Friend, 1962) as “freedom from danger, injury, or damage.” A suitable new term for a more expansive quality may be *robustness* or the more recently popular term *resilience*, which Webster defines as “ability to bounce or spring back into shape...after being pressed or stretched” (Guralnik and Friend, 1962). While safety relates to protection of the workforce and public from hazards within the plant, resilience relates to protecting the plant itself—ensuring that the financial investment and the generating capacity are not lost after a major event. As an example, the accident at the Three Mile Island nuclear plant in Pennsylvania in 1979 (Skillman and Rempe, 2021) resulted in no direct impact on the workers or the public (other than extreme anxiety); however, the damage to the reactor core was a financial disaster for the plant’s owner. Said differently, if a plant can survive a major upset intact, protection of the workforce and public will also be ensured. Realizing this distinction, many SMR designers seek to design for plant resilience.

Designing for resilience

Design choices impact its safety characteristics and also its resilience. Compare a delicate wine chalice and a beer stein: both are fundamentally used for serving an alcoholic beverage but the stein is considerably more robust. Similarly, engineered systems can be designed with robustness in mind or not. Many SMR designers understand this principle and design to a high level goal of significantly enhancing the resilience of their design, even if they articulate it as enhanced safety. Mario Carelli did this with his “safety by design” approach for the IRIS design (Carelli et al., 2004) and Jose Reyes is doing this for the NuScale design (Reyes, 2012).

Nuclear plant resilience fundamentally comes down to one requirement: keep the reactor fuel below its failure temperature at all times. If the heat produced in the reactor is successfully removed, the nuclear fuel remains intact and there are no bad consequences. Some reactor designers address this requirement by using a reactor fuel with very high temperature tolerance. Other designers focus on assured removal of the heat. Smaller sized reactors offer more options to address the heat removal requirement by the simple fact that there is less decay heat to remove and more options for removing it. Different SMR vendors have chosen a variety of ways to capitalize on this advantage.

Despite the diversity of SMR designs, many of them share a common set of design principles to enhance plant safety and resilience. The top-level principles include: (1) eliminate as many features as possible that have the potential to initiate a serious accident, (2) for those features that cannot be eliminated, reduce the probability that an accident will be initiated, and (3) design the system to substantially mitigate the consequences of remaining potential accidents.

An example of principle (1) is the integral primary system design approach in which all or nearly all of the primary system components are contained in a single pressure vessel. Fig. 2 shows a simplified comparison of a loop-type pressurized water reactor (PWR) design typical of most large operating reactors (Brown, 2021) and an integral primary system design, sometimes referred to as an iPWR. An integral configuration greatly simplifies the design in two ways: (1) it eliminates the external piping and vessels, and (2) it eliminates the need for active backup safety systems required to mitigate the extreme consequences resulting from a major break in any of the external pipes or vessels. These design changes not only increase the plant’s robustness but also reduces construction costs and operational costs associated with the eliminated systems.

A comprehensive review of many design features for small and medium sized reactors spanning all reactor technologies is given in a 2009 report issued by the International Atomic Energy Agency (IAEA) (IAEA, 2009). Some of the specific features that help to implement these principles and achieve a higher level of plant resilience include: the use of passive systems (rely on natural forces such as gravity, conduction and convection), arrangement of the primary system components to eliminate accident initiators, provide assured removal of decay heat produced within the reactor core.

An important consideration emphasized by the accident at the Fukushima Dai-ichi plant in 2011 (Mizokami and Rempe, 2021) is associated with the importance of having assured backup electricity in the case of a reactor upset. This vulnerability is well known and designers provide redundant layers of backup power options, including emergency diesel generators and safety-grade batteries. The power is needed to run pumps that circulate the cooling water and to operate valves that direct the various sources of cooling

Fig. 2 Comparison of traditional loop reactor design (left) with integral reactor design (right).

water to the required locations. A more elegant solution to this plant vulnerability is to eliminate the need for backup power, at least for maintaining the reactor core cooling function. Because of the smaller amount of decay heat within an SMR, it is practical to design the reactor system to not require backup power for extended and potentially unlimited time. In the NuScale design, this is accomplished by eliminating pumps entirely from the primary reactor system and immersing the module directly into a large pool of water to provide assured flow of heat from the reactor core to the ultimate heat removal system. In 2018 as part of the on-going review of NuScale's design certification application, the NRC formally agreed with NuScale that no safety-grade power source is needed to achieve safe shutdown of its modular reactors—a landmark accomplishment in nuclear plant resilience.

Another consideration, which is related to the previous issue, is the broader concept of "grace period." The grace period is the length of time after an accident during which no external power, make-up water, or operator action is required to maintain the plant in a safe condition. Initially, 24 h was used as the acceptable grace period, although newer plants are expected to provide a 72 h grace period. The accident at Fukushima demonstrated that more than 72 h may be needed in severe accident situations. The devastating tsunami made access to the plant by emergency workers very difficult. The few workers that were available were heavily burdened by the many actions needed to deal with the accident progression in four large reactor units. In recognition of this challenge, and due to the smaller heat loads and radionuclide inventories in SMRs, several designs appear to have achieved severe accident grace periods of several weeks. At least one water-cooled design (NuScale) offers an unlimited grace period, owing largely to its small module size of only 60 MWe and the fail-safe nature of its simplified emergency core cooling system. The modular high-temperature gas-cooled reactor (MHTRG) also promises unlimited grace period by virtue of its highly robust fuel form and assured removal of the decay heat (Shenoy et al., 2012).

The enhanced resilience that many SMR designs offer is perhaps the most significant benefit that SMRs can bring to the nuclear industry and has the potential to catalyze a major redirection of the public's perception about nuclear power. Moving the dialog from *safety* to *resilience* will be an important step in developing the new methods and metrics that will allow the industry to confidently advance the resilience of new plant designs against a broader range of unexpected threats and allow the public to recognize its benefits. Most likely, the first discernable impact of this enhanced resilience will be seen by the general public as a simplified emergency planning associated with new SMR builds—a crucial consequence of design resilience. The relationship between design resilience and emergency planning is discussed more thoroughly in Section "Financial risk."

While many studies have concluded that SMRs can provide exceptional safety and robustness, the consistent concern in these studies has been that the enhanced resilience comes at a price and the price is economic viability. The next section addresses this concern and offers justification for why improved economics will in fact be another significant benefit that SMRs bring to the nuclear industry.

Affordability and investor acceptance

Given the admirable safety record demonstrated by the nuclear industry over the past few decades, economics has now replaced safety as the greatest challenge and uncertainty for expanding the use of nuclear power. This concern is further exacerbated for SMRs due to a lack of direct experience with their construction and operation, and a prevailing mindset that "bigger is better"

(or at least cheaper). Consequently there have been several studies in recent years generating a plethora of papers and reports dedicated to proving or disproving the economic viability of SMRs. Unfortunately, the results and conclusions from the many studies are quite diverse, sometimes contradictory and frequently lack a clear understanding of SMR fundamentals.

Alvin Weinberg, a pioneer in the development of nuclear power and a staunch promoter of new technologies, also recognized the importance of economics. In his book *The Second Nuclear Era*, he wrote: “Unless a forgiving reactor is affordable, no one will buy it” (Weinberg et al., 1985). He was speaking specifically about the new smaller sized, highly robust reactor designs that were emerging during the late 1970s and early 1980s. Many subsequent studies of smaller sized reactor designs by the IAEA and Nuclear Energy Agency (NEA) also identified potentially unfavorable, or at least uncertain, economics as the key concern for smaller sized reactors.

With the rapid reemergence of interest in SMRs in the past ten years, both the IAEA and the NEA have taken a fresh and more refined look at the anticipated economics of SMRs. Additionally, several research organizations have conducted studies related to SMR economics with varied emphasis on market potential, cost projections, economic competitiveness, and economic impacts. An excellent overview of SMR economic considerations is given in a recent paper entitled “Small modular reactors: A comprehensive overview of their economics and strategic aspects” by Giorgio Locatelli and colleagues (Locatelli et al., 2014). Sara Boarin and colleagues also provide a good foundation of SMR economic principles in Chapter 10 of the *Handbook of Small Modular Nuclear Reactors* (Carelli and Ingersoll, 2014).

From the nuclear power industry’s infancy, the dominant metric for evaluating the economic viability has been “levelized cost of electricity” (LCOE). Roughly speaking, this is the total life-cycle cost of the plant normalized by the total energy production of the plant and is usually expressed as cents per kilowatt-hour (or dollars per megawatt-hour) (Rothwell, 2021). This metric continues to be appropriate for large capacity plants, which are typically located on extensive inter-connected grids with a robust wholesale electricity market. In this environment, the unit cost of electricity from each plant must be competitive with electricity generated by other plants—nuclear or otherwise—in the same wholesale market. While the LCOE metric makes sense for large plants, it is not obvious that it is equally important for SMRs, especially for those that are located on smaller regional grids or used for off-grid applications. Even for large-grid applications, it is necessary to expand the set of economic metrics in order to capture the new features that SMRs bring to the market, especially those that reduce investor risk such as incremental capacity growth.

A few recent studies have acknowledged the need for better economic metrics for SMRs (Rosner and Goldberg, 2011; NEA, 2011a). The collective studies highlight several financial metrics that are important to a fair assessment of the economic viability of SMRs, including:

- *Upfront capital cost.* This metric is basically the purchase price of the nuclear plant. It is central to the affordability of SMRs and is perhaps the leading discriminator between customers today who can consider building a nuclear plant and customers for whom this is not an option.
- *Interest during construction.* This metric is a subset of the total project cost and represents the cost of borrowed money. It includes several considerations such as availability of money, credit rating of the owner, length of construction, total debt, and overall project risk.
- *Maximum cash outlay.* This metric, similar to capital-at-risk, is the largest amount of debt that has to be financed at any time during the project and influences the interest rate of borrowed money.
- *Time to first revenue.* This metric helps to capture investor risk concerns, especially return-on-investment and financing costs.
- *Sensitivity to market changes.* This metric also captures investor risk concerns and impacts the uncertainty of the potential return on investment once the plant is operating.

Specific examples of these metrics, as well as the traditional LCOE metric, are discussed in the following sections to better characterize the potential economic viability and competitiveness of SMRs.

Affordability

Purchase price matters. Utilities have limits on what they can responsibly finance and what their investors or public service commissions will allow. The high cost of current large nuclear plants and the fragmented utility structure in the U.S. are driving a situation in which only the few most affluent utilities can consider building new nuclear plants. This effect is portrayed in Fig. 3, which compares the capital cost of four different energy sources: a multi-module SMR, a large dual-unit nuclear plant, a natural gas plant and a coal plant. Cost data for the latter three plants were taken from an Energy Information Administration report. (EIA, 2013) The cost range shown in the figure for the SMR was gleaned from publicly available data for some near-term SMRs that are under development in the U.S. Fig. 3 also shows the average annual revenue of all US investor-owned nuclear utilities (Rosner and Goldberg, 2011). The reality is that the purchase of a dual-unit large nuclear plant, similar to the plants being built in Georgia and recently abandoned in South Carolina, is a “bet the company” proposition for the larger utilities and is beyond consideration for smaller utilities. Although producing significantly less power than the large nuclear plant, an SMR offers a purchase price that is within reach of a smaller utility and may better match their capacity needs.

Another aspect of affordability is the flexibility to purchase an item incrementally. A group at the Politecnico di Milano (POLIMI) has been very active in the economic assessment of SMRs and developed the “integrated model for the competitiveness assessment of SMRs—the INCAS code.” Fig. 4, which is derived from their analyses (Boarin, 2015), shows an example of the impact of a staggered deployment of an SMR using INCAS-generated data provided by POLIMI. Three cases are presented: (1) a compressed

Fig. 3 Comparison of power plant investment costs for different energy sources.

Fig. 4 Impact of staggered build-out on maximum cash outlay (Boarin, 2015).

build-out of four 300 MWe single-unit SMR plants with a one-year overlap of each consecutive three-year SMR construction, (2) a protracted build-out of the same four SMRs with a two-year gap between consecutive plant constructions, and (3) a single 1,200 MWe plant with a 5-year construction duration. Both the SMR and large reactor were assumed to be PWRs. The construction schedules are depicted in the upper portion of Fig. 4. In the lower portion of the figure, the cumulative cash outlay profiles for the two SMR cases are compared to the large reactor cash outlay. The maximum cash outlay for the large reactor occurs in year 5 and is approximately 3,800 M€ (million euros), which is the full amount of the plant's construction cost. For the compressed SMR build-out case, the maximum cash outlay is reduced by roughly 30% to 2,700 M€, which occurs in year 8. The reduction in peak cash outlay is a consequence of the fact that revenue is being generated by the earlier SMRs while the latter units are being constructed, thus increasing the amount of self-financing. This effect is even more apparent in the protracted build-out case, which results in

a much smaller and flatter cash outlay profile. In this case, the maximum outlay is only 1,600 M€—nearly 60% lower than the large reactor case.

It is important to note that the three cases in this example result in different rates of new capacity addition to the grid. In the large reactor case, the full 1,200 MWe of generation is available at the beginning of year 6, while this does not occur with the SMR cases until year 10 for the compressed schedule and year 19 for the protracted schedule. However, if the reduced rate of cumulative capacity is acceptable to the plant owner based on demand growth, then the added flexibility of staggering the construction of the individual SMR units can have a significant impact on the owner's maximum debt. This, in turn, can help to reduce overall project cost by reducing the cost of financing the plant.

Economic competitiveness

Economic competitiveness of SMRs continues to be their most hotly contested feature. The controversy is probably a result of many factors, foremost of which is an ingrained mindset in the nuclear industry favoring economies of scale. As discussed earlier, LCOE quickly became the dominant metric in the early phases of the nuclear industry. It was also widely assumed that LCOE is lowest for large plants due to economies of scale. However, the fixation on economies-of-scale principle actually drove the industry in the opposite direction, i.e. it generated a succession of larger and more complex plants that ultimately resulted in a higher unit cost of electricity.

Economies of scale have been demonstrated repeatedly in many industries. Every system designer must contend with this reality. However, a closer look at the economics of SMRs suggests that the economies-of-scale factor can be substantially mitigated by a combination of other economic considerations. One of the earliest studies of the “economies of small” was conducted by Hayns and Shepherd of AEA Technology during the time of the development of the Safe Integral Reactor design (Hayns and Shepherd, 1991). They provided a qualitative discussion of a dozen factors that can offset economies of scale in SMRs, which are paraphrased in Table 2.

In another study, Ning Li recognized the importance of design simplification (Li, 2009). He cites the example of emergency core cooling systems, which are added to a nuclear plant to protect against the severe consequences of a loss-of-coolant accident. He argues that the lower power rating of an SMR results in design solutions that allow simple passive systems to suffice. In contrast, large (high power) plants require sophisticated active emergency core cooling systems.

In the case of the NuScale design, the unique integrated module configuration and small unit power—just 60 MWe—allows 15 major systems or components found in traditional PWR plants to be eliminated while introducing only one new system. A recent study by the Energy Policy Institute at Boise State University compared detailed cost information for a NuScale plant against a standard 4-loop PWR (Black et al., 2019). As expected, the NuScale plant was significantly less expensive than the PWR on an absolute basis—less than half the total capital cost. Surprisingly, it was also found to be less expensive on a per-unit-output basis. The normalized direct capital cost (structures, equipment, etc.) was similar for the NuScale and PWR plants, while the normalized indirect capital cost (design services, construction supervision, etc.) was 68% lower for NuScale, yielding a total capital cost that was 38% lower than the large PWR cost. They attribute the cost savings to the “modular design and off-site manufacturing that dramatically reduces the on-site construction activities.”

Another consideration regarding the competitiveness of SMRs is operating cost. Given the complete lack of experience in the operation of any contemporary SMR designs, anticipated operating costs are highly speculative and generally lacking in the

Table 2 Factors that can mitigate economies-of-scale in an SMR.

<i>Factor</i>	<i>Description</i>
Increased factory fabrication	Smaller unit size permits a greater degree of factory fabrication and less on-site construction to reduce labor cost
Skilled work force retention	Increased factory fabrication will help to attract and maintain skilled workers without drawbacks of frequent relocations
More replication	Production of a larger number of small standardized units increases efficiency of fabrication/construction
Multiple units at a single site	Shared infrastructure at a common site can reduce capital cost per installed unit
Improved availability	Multi-module plant using smaller reactor modules improves the possibilities for partial operation of the plant during maintenance of a single module
Learning curve	A larger number of small identical units expedites achieving fabrication/construction efficiencies through learning process
Bulk ordering	A larger number of small units can reduce cost of bulk orders for individual components
Better match to demand	Small unit size allows better match to demand, thus reducing costs associated with purchased power or stranded assets
Smaller front-end investment	Smaller total project cost reduces construction financing cost
Reduced construction time	Shorter construction time reduces construction financing cost and introduces revenue sooner
Increased plant lifetime	Small modules may lead to easier refurbishment/replacement costs and extend lifetime of the facility
Reduction in planning margin	Smaller unit capacity shortens planning horizon and reduces investment sensitivities to market changes
Design appropriate to the size	Small unit size can enable simplification of systems and reduce costs of materials, fabrication, maintenance and disposal

open literature. There are reasonable bases for speculating that SMR operating costs will be higher due to a lack of scaling of labor force requirements; however, there are also valid bases to speculate that innovations and efficiencies in operations will more than compensate. Given that even the most mature contemporary SMR designs are still in the licensing or construction phases, it may be more than a decade before substantiated data on operating costs are obtained.

Financial risk

Total project cost is clearly the dominant factor in the purchase of a nuclear power plant. However, financing risk is also a major consideration, especially in merchant markets. The bigger the risk, the higher is investor concern and the more they charge for using their money. Also, as risk increases, some financing options disappear such as venture capital money, which are typically smaller investments (less than \$100M) with an expectation of rapid pay-back (less than 5 years). In contrast, bringing a new nuclear project to reality generally costs billions of dollars and may require decades before the first dollar of revenue is generated.

Undeniably, nuclear power conjures up a higher perception of risk to the investor community than most other industrial endeavors. This perception was articulated at a 2009 workshop on financing of nuclear projects as part of the Global Nuclear Energy Partnership (GNEP) program. Several individuals were invited from the financing community, including Deutsche Bank, Fitch Rating Services, Towers Perrin, Nippon Export and Investment Insurance, and the U.S. Export-Import Bank. These representatives shared a consistent message: nuclear projects are among the most difficult for investors to embrace. Some of the more common justifications included the capital-intensive nature of nuclear projects with very long payback times, impact of external factors such as regulatory uncertainties and public response, construction delays and cost overruns, and the need for reliable long-term market forecasts. In Grubler's paper on the French nuclear program, he writes: "Perhaps the nuclear 'valley of death' is its inherently high investment costs and their tendency to rise beyond economically viable levels" (Grubler, 2010).

The POLIMI group also assessed financing risks associated with nuclear power projects (Carelli and Ingersoll, 2014). They cite many of the same issues that were voiced by the bankers at our GNEP meeting, which they categorize into those that are associated with capital-intensive projects and those that are unique to nuclear projects. Their major risk factors are delineated in Table 3.

The POLIMI group further asserts that construction cost and schedule overrun is the leading factor that contributes to nuclear project risk. As mentioned earlier, total project cost is highly sensitive to construction duration. The most significant component of this sensitivity is financing cost, but other cost factors can contribute such as retention of the labor force and protracted rental fees for major construction equipment. The inherent features of SMRs mitigate many of the risks. These include shorter construction time, faster time to first revenue, and higher reliability in fabrication costs and schedule. The shorter construction time and sequential construction features also result in lower sensitivity to several market-related factors such as interest rates, electricity prices, and changes in electricity demand due to the owner's ability to respond faster to changing conditions. Of special note was the fact that the combined effect of shorter construction time and reduced capacity of an SMR helps to mitigate the impact of miscalculating the long-term forecast of electricity demand, which can result in the purchase of expensive replacement power or result in a stranded asset—either of which hurts the plant's profitability.

While SMRs appear to have a clear advantage over single large plants in terms of reducing investment risks listed in the left-hand column of Table 3, it is less obvious that they will have any impact on the nuclear-specific risks. Their ability to impact these factors will depend substantially on the successful licensing and deployment of the first SMRs in terms of demonstrating the first two major strengths of SMRs: their enhanced safety/resilience and their affordability. If this can be done for traditional electricity applications, it will enable realization of the third major benefit of SMRs: their suitability for expanding the use of nuclear power to non-traditional markets and non-electrical applications—the topic of the next section.

Flexibility and owner acceptance

Small modular reactors are not generally intended to compete with large plants. Many SMR designs are motivated by the opportunity to expand the use of nuclear power to more diverse customers and applications. In some cases, the SMR features that enhance

Table 3 Major risk factors impacting financing of nuclear power plant projects.

<i>Common to capital-intensive projects</i>	<i>Unique to nuclear power projects</i>
• High up-front capital costs • Cost uncertainty • Construction supply chain risks • Long lead times and long payback periods • High sensitivity to interest rates • Plant reliability and capacity factor • Market price of product (electricity)	• Unstable public support • Negative public acceptance • Regulatory and policy changes • Decommissioning/waste disposal costs and liabilities

Carelli MD and Ingersoll DT (2014) *Handbook of Small Modular Nuclear Reactors*, Cambridge, UK: Woodhead Publishing.

their adaptability to non-traditional plant owners also enhance the usability of the plant for even the traditional users. The first two features of SMRs that help to provide their expanded flexibility are captured in their name: small and modular. Two additional features that are derived from their smallness and modularity are worth highlighting: their benefits for more flexible plant siting and their adaptability to non-electrical applications. All four factors, which are discussed in more detail in the following sections, contribute to the promising potential that SMRs offer to better accommodate the needs of both traditional and non-traditional owners.

Size considerations

There are some applications for which an SMR (with output typically greater than 50 MWe per module) is actually too big for the energy demand. These include customers such as small isolated communities, single industrial facilities, mining operations, and defense installations. For these applications, there is an emerging class of reactors referred to as micro-reactors with power outputs generally below 10 MWe (Wallenius, 2021). Although SMRs may not be a solution for the very small consumer, there are many cities and industrial complexes that have significant electrical demand, but for which large nuclear plants or other energy alternatives may not be practical. Some of these communities may have access to adequate electrical grids but many more have outgrown their local grid infrastructure or have only marginal grid interconnection. For these customers, SMRs offer a very promising solution, suggesting the value in a more distributed power generation model than conventional nuclear allows.

Installing new overhead high-voltage lines can cost \$1–2 million per mile and the cost of underground lines can be four to five times higher. In some locations such as the western U.S., it is especially challenging to add new transmission lines. Whether because of the vast amount of protected lands, the harsh topology, or safeguarding of protected species, the acquisition of new transmission right-of-ways and the construction of the lines are both difficult and expensive. Extended transmission lines also create grid vulnerabilities since they can be disrupted by severe weather or sabotage. Recently in California, downed power lines have contributed to devastating fires. This reality highlights a significant benefit of an SMR's smallness: its small unit output allows for a more distributed model of nuclear power generation than currently exists. In other words, SMRs are about offering more choices to the utility executives, not only choices among power generation options but also the choice between distributed generating assets versus new transmission and distribution networks.

Having smaller sized generators also helps to provide grid stability, especially in regions with limited grid interconnection. An often-cited rule-of-thumb for stable grid operation is that the output of a single generating unit should not exceed 10% of the total generating capacity. Even in large grid regions, utilities are accustomed to operating smaller sized generating units. Fig. 5 shows the size distribution of all types of electrical generation plants worldwide, which indicates that roughly 93% of the generating plants have capacities below 500 MWe (Research and Markets, 2006). Even in the U.S., only six of the nearly 1,400 new generating units added between 2000 and 2005 had power ratings of greater than 350 MWe. Consequently, most utilities are very familiar with the operation and grid management strategies for smaller generating units.

Related to this is the requirement for “spinning reserve,” which is the excess capacity that must be available to the utility to accommodate the loss of the largest generator on the system without major disruption. Large, single-unit generating plants dictate

Fig. 5 Size distribution of electricity generation plants globally (Research and Markets, 2006).

the need for a large amount of spinning reserve. This can be accomplished by running many of the existing stations at slightly less than full capacity, or by operating dedicated units on continuous standby. Either way, energy is being wasted. The smaller output of an SMR provides a more manageable power distribution and reduces wasted resources associated with the spinning reserve capacity.

Also related to the integrity of the grid infrastructure is the issue of load-following, i.e. adjusting generator output to match demand fluctuations. Conventional wisdom suggests that nuclear power plants should be operated continuously at full capacity and that natural gas plants are best suited to provide “peaking” capability to meet excess demand. This historical strategy has been driven largely by economic considerations. The logic is that because a nuclear plant has a relatively high capital cost and relatively low fuel cost compared to a natural gas plant, it makes sense to keep the more expensive hardware running continuously. Because of its low fuel cost, running the nuclear plant at 50% power has minimal impact on its operational costs but cuts revenue in half. Increased maintenance costs are also normally higher with load-following operation due to fatigue issues introduced by the thermal cycling of the reactor and balance-of-plant systems.

Some coal plants, which also operate best at full power, are now being cycled for load following in the U.S. and nuclear plants are expected to follow. Worldwide, France’s pressurized water reactors load-follow on a regular basis due to the high percentage of nuclear-generated electricity on their grid (nominally 75%). Canadian reactor units are also required to load-follow due to the relatively high percentage of nuclear power there and German reactors load-follow primarily because of a relatively high contribution of intermittent wind generation on their grid (NEA, 2011b).

There are now two reasons to consider load-following with SMRs. The first is for small grid applications enabled by SMRs. In these cases, similar to what is experienced in France and Canada, the relatively high percentage of nuclear generation on the regional grid will likely force the SMRs to follow the changing demand. The second reason to consider load-following with nuclear plants is in response to an increasing penetration of renewables on the grid, similar to the situation in Germany. The increasing penetration of renewable sources, especially wind, has altered the economic argument since wind turbines are also capital-intensive (more expensive than nuclear plants per unit of power produced) and their fuel cost is very low—zero, in fact. Also, some regional policies require grid dispatchers to preferentially use renewable energy first, thus requiring baseload plants to accommodate demand variations. Consequently plant owners are already beginning to perform power maneuvering with coal plants and are being pressured to extend this to nuclear plants.

Fortunately, the smallness of a typical SMR allows it to better accommodate load-following operations and several vendors advertise this capability. In general, load-following impacts are reduced relative to large plants because of the greater agility of the plant to respond to thermal cycling. The greater agility is provided by the smaller reactor system components, smaller turbine/generator equipment, and system simplifications that are enabled by the smaller reactor size. Fast spectrum reactors such as sodium-cooled SMRs (Heide, 2021) have a further advantage that the core reactivity is much less sensitive to xenon buildup and depletion in the reactor core, a phenomenon that complicates core power maneuvers in thermal spectrum reactors such as water-cooled reactor systems.

Modularity (scalability)

Related to small size is the equally important factor of modularity. They work together to provide a scalable solution to meet a wide range of potential applications. Successful examples of modularity exist throughout the energy industry. The world’s largest solar farm, which was recently completed in California, produces over 500 MWe from nine million individual solar panels. Multi-gigawatt wind farms are built from thousands of 1–2 MWe wind turbines. Also, many coal plants are comprised of multiple small boilers such as the 1,400 MWe Kingston Steam Plant in Tennessee that uses nine 175–200 MWe boilers. In fact, nuclear appears to be the last holdout in the energy industry for the sole use of large single-unit power generating stations.

Multi-module plants allow the owner to build new capacity at a rate that more closely matches demand growth and allows the local grid capacity to be built up in modest increments. This provides the owner with operational flexibility and favorably impacts the economics of the plant, as discussed in the previous section. Besides the economic advantages of reduced cash outlay and better demand matching, modularization of nuclear plants provides an opportunity to take standardization to a new level. The U.S. did a dismal job at standardizing nuclear plants in our original build-out during the 1960s and 1970s. Nearly every plant was a unique design. Subsequent nuclear build-outs in countries such as France and the Republic of Korea have done a better job at maintaining standardization in their fleet of commercial reactors with an observable gain in improved efficiencies and reduced costs. The new plants being built in the U.S. also anticipate improved standardization, but it is too early to tell if the vendors and new customers will adhere to this goal. Modular plants facilitate the possibility of a highly standardized reactor system by virtue of their intrinsic multiplicity within a plant, smaller component sizes, and a higher fraction of factory-fabricated components.

The higher degree of reactor system standardization that SMRs can provide should also accelerate the implementation of fleet-wide system management, similar to what is done in other industries such as jet engines in the aircraft industry. Rolls Royce is able to monitor a large array of operating parameters on thousands of in-service jet engines using sensors and live satellite feeds to predict potential problems before they occur (Rolls Royce, 2015). The ability to monitor the operating condition of each module in real time could further enhance plant safety through early identification of component aberrant behavior and allow for timely repair or replacement. A further simplification and economic advantage of operating a fleet of standardized modules is the efficiencies gained in maintaining a reduced inventory of replacement parts and qualification of maintenance personnel.

Siting flexibilities

A significant siting flexibility of SMRs, if it can be realized, is the opportunity to simplify the plant's emergency management plan, including potential reduction in the plant's emergency planning zone (EPZ). The NRC currently sets the EPZ for existing and new nuclear plants at 10 miles for plume exposure and 50 miles for ingestion pathways. However, they allow a license applicant to request a reduced EPZ and have licensed several small reactors with an EPZ of 5 miles. These include the Fort St. Vrain (842 MWt), Big Rock Point (240 MWt) and La Crosse (165 MWt) plants, although none of these plants are still in operation (INL, 2014). As discussed in a previous section, new SMR designs are expected to have significantly enhanced robustness against accidents, which results from innovative engineering and extensive use of passive safety systems. They also will have reduced accident source terms by virtue of a smaller reactor core size and may include additional barriers for fission product release if fuel damage does occur. Hence, it should be possible for an SMR to justify a reduced EPZ size while not increasing risk to the general public.

In recognition of this opportunity and its value, the SMR community has been working through the Nuclear Energy Institute (NEI) to develop and pursue a methodology for deriving the appropriately "optimized" emergency preparedness of an SMR that is commensurate with the plant's relative risk. The NEI submitted a whitepaper on the topic to the NRC in December 2013 describing a methodology for establishing a "technology-neutral, dose-based, consequence-oriented emergency preparedness framework for small modular reactor sites" (NEI, 2013). The methodology requires that a license applicant provide a substantiated technical basis for the proposed emergency planning actions, including the extent of the EPZ.

The first test case for the new methodology was an early site permit application submitted by the Tennessee Valley Authority (TVA) in 2016. As part of their application, which enveloped four SMR designs, TVA proposed a scalable EPZ and supported their proposal with results from a NuScale analysis using the new methodology. In another landmark accomplishment for SMRs, the NRC staff concurred with a site boundary EPZ for a NuScale design.

Optimization of the EPZ for SMRs is valuable for a number of reasons. First, a recent analysis at the Idaho National Laboratory determined that the average cost of establishing a 10-mile EPZ averages about \$10M per plant and adds greater than \$2M to the annual operating cost (INL, 2014). A substantial portion of these costs would be saved if a reduced EPZ can be justified. More importantly, a reduced EPZ facilitates siting of the plant closer to population centers without the costly and socially alarming aspects of emergency planning requirements. This is especially important if SMRs are to be successful as an option for distributed power generation for smaller, more remote communities. A reduced EPZ will also help to facilitate broader missions for SMRs, especially process heat missions. In this case, co-location of the reactor with the industrial user is very important to minimize heat losses due to lengthy steam distribution lines. This brings us to the fourth major flexibility that SMRs have to offer its owner: suitability for non-electrical applications.

Non-electrical applications

A significant attractiveness of small reactors is their flexibility to enter traditionally non-nuclear energy markets. Several energy-intensive applications could significantly benefit from using nuclear-generated heat to replace the combustion of fossil fuels to produce heat. This would not only reduce emission of greenhouse gases, but would also allow the fossil resources to be used as feedstock for producing higher value products such as petrochemicals and plastics. In the U.S., electricity generation contributes only 40% to our total carbon emissions, so a concerted effort to reduce our total emissions will necessarily require replacing fossil fuels with non-emitting fuels in the industrial sector as well as the electricity generation sector.

The suitability of SMRs for this mission is largely a result of their smallness and modularity and to a lesser extent their siting flexibilities. Primary applications for nuclear heat include:

- District heating and cooling
- Water desalination and purification
- Advanced oil recovery processes and oil refining
- Hydrogen production for the enrichment of liquid fuels and eventually fuel cell applications
- Advanced energy conversion processes such as coal-to-liquids and petrochemical production
- General process heat for chemical or manufacturing processes

In all cases, smaller sized, more robust reactors are better suited for integration with these applications than are large plants because of the many considerations discussed earlier.

The most logical integration of a nuclear plant with non-electrical applications is to co-locate the two facilities and dedicate the nuclear plant to the industrial facility. The energy coupling may be heat only or a combination of heat and electricity. The latter arrangement is typically referred to as either "co-generation" or as "combined heat and power" (CHP). The aspect of co-location is what gives SMRs a distinct advantage over large power plants because their smaller output is typically a better match for a single industrial plant. Co-location is further facilitated by the reduced emergency planning zone for some SMRs, as discussed in the previous section. The International Atomic Energy Agency (IAEA) has conducted a number of studies of non-electrical applications for nuclear plants, including for traditional water-cooled reactors and advanced non-water-cooled reactors. An especially thorough review on the subject for water-cooled reactors is reported in *Advanced Applications of Water-Cooled Nuclear Power Plants* issued in 2007 (IAEA, 2007). Non-water-cooled SMRs also are attractive for non-electrical applications, especially due to the higher temperature output of gas-, metal- and salt-cooled reactors.

Another operational flexibility with smaller nuclear plants is the ability to better match the plant output to the user requirements, which is especially valuable for process heat applications. Many process heat users actually require a relatively modest

amount of heat—far less than the 3,000–4,000 MWt that a large nuclear plant produces. For example, a 2008 study by Greene concluded that a nuclear plant producing approximately 100 MWt is sufficient to provide all the process heat needed for the production of liquid fuels in a state-of-the-art biorefinery (Greene et al., 2008). This modest heat demand is a result of the fact that the biorefinery size is dictated by the transportation cost associated with transport of the bulk biomass, which limits the reach of the feedstock supply to about 50 miles. Similar results were reported in a NuScale study, which found that a large commercial-scale water desalination plant producing 190,000 m³/d (50 million gallons per day) of clean water consumes between 150 and 550 MWt, depending on the choice of desalination technology (Ingersoll et al., 2014). Finally, a paper published by the European Commission's Joint Research Institute indicates that in the European industrial market, the average thermal demand per site of several industrial processes ranged between 100 and 400 MWt. This included factories for the production of various products such as chemicals, cement, iron and steel, soda ash, and alumina (Carlsson et al., 2012).

Bringing promises to reality

Despite the several benefits of smaller sized reactors and their potential to positively impact the broad acceptance of nuclear power, many technical and institutional challenges must be addressed and overcome. From a technical perspective, design innovations, such as integral primary systems and passive safety systems, will require comprehensive testing and demonstration through separate effects tests, scaled simulators, or perhaps even a prototype unit. Examples of some non-traditional components include helical coil steam generators, internal control rod drive mechanisms and internal coolant pumps. Much of the required testing has been done for the NuScale SMR but will need to be similarly demonstrated for other new water-cooled designs. In the case of the non-water-cooled designs, significant material and fuel qualification efforts may be needed in addition to new component and systems testing. Material and fuel qualification will be especially important for SMR designs that are intended to have very long fuel cycle lengths—some designs claim cycle lengths as much as 10 to 15 times longer than current LWR fuels.

A number of institutional challenges also exist for the deployment of new SMR designs. The most significant challenge will be the regulatory approval of the new designs. As mentioned in the previous section, the NRC is already working to adapt the existing licensing framework to SMRs, including those that use advanced technologies; however, there are many explicit and implicit biases in the process in favor of large light-water reactor plants. The NRC is currently working to expand the framework to be both size and technology neutral (Rempe and Williams, 2021).

Summary

In the past decade, a number of new SMR designs have emerged that promise notable improvements in safety and resilience, construction, operations and affordability, and also are well suited for a variety of energy-intensive applications. All of these benefits have the potential to significantly impact the acceptability of nuclear power. Improved safety/resilience is accomplished by lower fuel inventory, greater use of passive safety features, and the elimination of design features and components that are vulnerable to potential accidents. Lower total capital cost, extensive factory fabrication, and shorter construction time contribute to reduced investment risk and cash outlay profiles, thus addressing affordability. Finally, the smaller physical size and modularity contribute to added flexibilities in fabrication, construction and plant siting. If realized, these improvements should produce a discernable improvement on the acceptance of nuclear power from all stakeholder groups, including the general public, investors, and plant owners. In short, successful demonstration of the SMR promise provides an opportunity to significantly change the nuclear dialog.

Introduction

Floating nuclear plants have been used since the 1950s. Nuclear submarines, aircraft carriers, and ice breakers have been powered by nuclear plants for over 60 years. So it is not unreasonable to consider such plants for commercial nuclear electricity power production. This is becoming especially important as sites for new electricity generation are becoming limited forcing companies to look at offshore locations for electric plants. Off shore wind generators have led this trend which provides a solution to visual pollution and disruption of television and other electronic signally devices which typically are reasons for siting objections to wind turbines. In the case of nuclear energy, objections by people who may not want a nuclear facility in their neighborhood is a driving force for moving these plants offshore—10–20 miles away. This distance also reduces the need for emergency planning of civil populations in the unlikely event of an accident. Offshore locations also enhance safety by providing a vast reservoir of cooling water and has security advantages due to its isolation. Additionally, factory manufacture can lower the capital cost of new nuclear construction much as it has lowered the cost of modern nuclear submarines using modularization techniques. There are also non-proliferation advantages for floating nuclear plants in that nations do not need to build enrichment or reprocessing plants since these services could be provided by the vendor or operator.

At present, Russia is the leader in developing an operable floating nuclear plant. With the launch in 2018 of the Akademik Lomonosov, a 60 MWe floating nuclear plant now operating in Pevek, a rural Siberian community, they have shown the feasibility of floating nuclear plants ([World Nuclear News, 2019](#)). This paper reviews current thinking about such plants discussing advantages and disadvantages leading to the conclusion that such plants offer many countries a flexible option to use clean nuclear energy safely avoiding many public objections ([Boyd, 2019](#)). Russia claims to have 70 orders for their Lomonosov type plants and China intends on building 20 floating nuclear plants. Presently countries developing floating nuclear plants, in addition to Russia and China, are the United States, Korea, and recently, Denmark.

History of floating nuclear plants

One of the first applications of floating nuclear plants was in 1967 with the installation of a nuclear reactor on the Sturgis (MH-1),¹ a converted Liberty ship, to supply electricity to the Panama Canal Zone ([Horizon Environmental Services, 2019](#)). This project started in 1961 with the installation and testing of a 10 MWe pressurized water reactor at Ft. Belvoir. This project was one of several

¹Mobile High Power.

conducted by the US Army Nuclear Power Program to employ nuclear energy at remote locations to supply power and heat for their outposts (US Core of Engineers, 2019). The ship was towed to the Panama Canal Zone to supply power to the Gatun Lake pumps to control water flow. The ship provided power from 1968 to 1978 during which it was refueled five times with low enriched uranium fuel. The Sturgis has since been decommissioned (Wikipedia, 2020d; Horizon Environmental Services, 2019) (Fig. 1).

The second most serious effort at designing and building floating offshore nuclear plants occurred in the United States in 1969 with the development of the Atlantic Generating Station whose concept was to use a factory much like a ship yard to build a full size 1150 MWe Pressurized Water Reactor on a 400 ft square barge drawing 30 ft which would be floated out to a location 2.8 miles off the New Jersey shore surrounded by a break water (Wikipedia, 2020e). An artist rendering of the concept showing twin barges is shown below.

Public Service Electric and Gas teamed up with Westinghouse and Tenneco to build this plant in a factory in Jacksonville Florida (Touran, 2020). The company formed was called Offshore Power Systems which filed an application with the Nuclear Regulatory Commission to manufacture these floating plants. A significant accomplishment was the issuance of a “manufacturing license” ML-1 for the factory to produce as many standardized floating plants as the market would order (Nuclear Regulatory Commission, 1982). This was revolutionary for an industry that was characterized by uniquely building each plant as “stick built” requiring extensive regulatory review. The goal of Offshore Power Systems was to take advantage of standardized mass production in a factory setting to offset on site construction costs and avoid siting disputes on the limited and highly populated east coast (Fig. 2).

As can be seen in the figure, the floating nuclear plant barges are moored behind massive breakwaters in 30 m of water. These breakwaters were designed for wave heights of 43 ft, 156 mph sustained hurricane winds and 300 mile/h tornados. Electricity would be cabled under water to the shore using AC power to a base that would be used to support plant operation several miles out to sea.

The design proposed also had significant safety advantages since the location in the ocean provided what is referred to as an “ultimate heat sink” for cooling water in the event of an accident. Its location offshore also provided additional margin of safety without requiring public evacuation in the unlikely event of a core damage accident. The Westinghouse designed plant was also supplied with a “core catcher” as an additional level of protection in the unlikely event of a meltdown preventing the release of radioactive materials.

The plants were first announced in 1971 with an initial order of two followed by another two in 1973. Unfortunately during this period the US was confronted with an Arab oil embargo and declining energy demand. In 1978 PSEG cancelled all 4 units despite the issuance of a manufacturing license in December of 1978. This license has since expired in 1999. The breakthrough of using a manufacturing license is important for future small modular reactors being considered in the United States.

The interest in floating nuclear plants has seen a recent resurgence as shown on Table 1. Many of these plants are still in the conceptual design stage. As can be seen, Russia is the leader using its nuclear ice breaker technology.

What problems could floating nuclear plants solve

Offshore floating nuclear plants are aimed at providing a flexible power source to remote communities, and nations, especially those that might not have the regulatory or technical infrastructure. In addition, they can avoid land siting problems, improve economics, provide additional safety margin and avoid national proliferation problems. They can provide a safe clean platform for varying size reactors to power cities without needing land resources. They have an overall increase in the level of safety, and hopefully public acceptance. They offer the opportunity for increased quality of construction and fabrication in factory environment. As land resources for power generation become scarce, developed nations might find such floating plants as suitable alternatives for bulk power production near load centers but offshore.

Fig. 2 Proposed Atlantic Nuclear Generation Station. Artist Rendering of PSEGC Design. Timeline.

From the generators point of view, the expectation is reduced cost of construction as a result of the shipyard environment with economies of production offsetting economies of scale. In addition, this onshore factory would provide the essential services needed for each nuclear plant in a central location, further reducing costs. Much of the cost of nuclear construction goes to civil and structural work which would be eliminated saving hundreds of millions of dollars for each plant. The advantages of standardization can also be fully realized in such a setting. These plants can be located where needed and when needed adding additional flexibility. They can be a significant part of the climate change solution for developing nations as well since the plants can be operated by the company selling the plants who would also be responsible for training, maintenance and refueling with the host nation only paying for the power. This could be very advantageous to developing nations as they seek to improve the quality of life for their people and avoiding proliferation concerns.

The bottom line goal of floating nuclear plants is to avoid local land use siting objections and challenges, gain public acceptance due to improved safety and reduce costs by building in central shipyards for world wide deployment.

Concept of floating nuclear plants

Floating nuclear plants are generally considered to be in the small modular reactor class of new nuclear plants. A proposal by researchers at the Massachusetts Institute of Technology is focused on designing an offshore platform that can house a full size 1000 MWe reactor plant among other sizes to address large load center needs. These plants depend on advanced manufacturing and assembly in factories instead of massive on site construction programs. Through such mass production, costs should be lowered allowing smaller reactors to be in a better position to be competitive with larger plants. In addition, these floating plants are typically barge mounted not requiring large civil structures which are typically found in land based plants. Most of the floating plants can be floated back to central maintenance or refueling facilities for periodic maintenance further lowering the operating cost by using common facilities. The offshore or undersea locations also provide additional safety due to the ocean being a source of cooling water should the plant suffer a loss of coolant accident. The greatest attribute seems to be one of siting since most opposition to nuclear plants comes when a local site is selected. Much as offshore wind turbines have reduced opposition to their siting, floating nuclear plants offshore might gain similar acceptance.

One of the major impediments to new nuclear deployment is the high cost of construction to meet detailed technical safety requirements. Small modular reactors, on a per unit basis, are more costly than larger plants due to the larger plant's economy of scale—more power for the footprint. To offset this disadvantage floating nuclear plants, like small modular reactors, rely on the economies of mass production to reduce the cost in addition to manufacturing in a central factory. The avoidance of many geological studies, site licensing processes, and civil structural work offer huge savings in time and money. It is estimated that at least 20% of the capital cost of a nuclear plant is associated with site preparation and civil works ([World Nuclear Association, 2020](#)). Also using the shipyards as central service centers for major maintenance is a savings in on site facility and operating costs. The barge only needs to be floated to the central location and returned when ready.

Review of existing designs

Countries currently active in the development of floating nuclear plants of many different types include the Russia, France, China, Korea and the United States and recently Denmark. These will be briefly described in this section.

Table 1 Summary of civilian offshore nuclear plants built or designed.

<i>Name</i>	<i>Reactor type and power rating</i>	<i>Operating conditions</i>	<i>Notes and references</i>
ABV—6M (Russia)	VVER Thermal power—38 MW Electric power—8.6 MW	Design pressure, — 15.7 MPa Design temperature — 330 °C Steam generation capacity—248 t/h Fuel material and enrichment—UO ₂ , 19.7% Superheated steam pressure /temp.— 3.14 MPa/290 °C	Integral reactors with 100% natural circulation in the primary circuit; modular design for both land-based and floating nuclear power plants
KLT—40S (Russia)	VVER Thermal power — 150 MW Electric power — 35 MW	Design pressure — 12.7 MPa Design temperature — 316 °C Core coolant flow rate — 2600 t/h Coolant temperature at core inlet/outlet — 280/317 °C Fuel material and enrichment — UO ₂ , <20% Superheated steam pressure/temp.— 3.8 MPa/290 °C Steam generation capacity — 2 × 240 t/h	Serial modular reactors for nuclear icebreakers and sea vessels; floating nuclear power plant
RITM—200 (Russia)	VVER Thermal power — 175 MW Electric power — 50 MW	Design pressure, — 15.7 MPa Steam generation capacity — 248 t/h Fuel material and enrichment — UO ₂ , <20% Superheated steam pressure/temp.— 3.82 MPa/295 °C	Integral reactor with forced circulation in the primary circuit for nuclear icebreakers
VK—300 (Russia)	BWR Thermal power — 750 MW Electric power — 250 MW	System pressure — 6.9 MPa System temperature — 285 °C Fuel material and enrichment — UO ₂ , 4.0%	Natural circulation in primary circuit
VBER—300 (Russia)	VVER Thermal power — 917 MW Electric power — 325 MW	System pressure/temp.— 12.7 MPa/316 °C Fuel material and enrichment — UO ₂ , 4.95%	Modular reactor based on marine propulsion reactor technologies for land-based and floating nuclear power plants
Atlantic generating station—Offshore nuclear power plant (United States)	PWR Electric power — 1150 MW Thermal output — 3425 MW	Operating pressure — 2250 psia Containment design Pressure — 15 psi Reactor inlet and outlet temp. — 557.3 °F/616.9 °F Fuel material and enrichment — UO ₂ , 3.2% No of coolant pumps—4 Total reactor flow — 142.1 × 10 ⁶ lb./h	Ice condenser containment; large breakwater; twin units
FLexBlue underwater power plant (France)	PWR Electric power—50–250 MW Thermal power—150–750 MW	System pressure — 15.5 MPa System temperature — 310 °C Fuel material and enrichment—UO ₂ , 3.1%	At conceptual design stage: autonomous operation, seabed, torpedo resistant
Offshore nuclear power plant (South Korea)	PWR Electric power—1400 MW × 2 units	Standard APR1400 PWR nuclear island with passive seawater-based containment and core cooling systems	Plant housed in concrete/steel structure resting on seabed, suitable only for shallow waters

Russia Akademik Lomonosov

As shown on Table 1, Russia has a number of such marine nuclear applications in addition to the ice breaker KLT 40S. This reactor design was used for their floating reactor barge plant—The Akademik Lomonosov which was launched in 2018 and placed in operation in 2020 at Pevek, Russia, a remote town in northern Siberia. An artist rendering of the plant is shown below. The actual photograph of the plant is shown as well (Power Technology, 2020) (Figs. 3 and 4).

This barge actually looks like a ship but needs to be towed to its desired location typically in a port. It is 140 m long with a 30 m beam and draft of 5.56 m. It displaces 21,500 t with a crew size of 70 people for operation and maintenance. The barge has two 35 MWe KLT reactors sufficient to power a city of about 200,000 people for 40 years. Additionally the ship can supply 300 MWth of heat to the community and can be converted to supply 240,000 L of fresh water each day.

France—FLEXBlue

The FLEXBlue plant has been under development in France for many years. This plant is being designed by DCNS² for undersea deployment to support on shore facilities (Gourmel et al., 2016). It is basically a submarine without engines carried or towed to

Fig. 3 Artist rendering of Akademik Lomonosov. <https://www.crediblecarbon.com/news-and-info/news/marine-nuclear-plant-leads-the-way-to-the-future/>.

Fig. 4 Actual photo of Akademik Lomonosov. Lev Fedoseyev—Lev Fedoseyev/TASS.

an undersea location where they are anchored to supply needed power. It is designed for autonomous operation with minimal

²Direction des Constructions Navales (DCNS) is predominately a French state owned defense contractor that designs, builds, maintains and decommissions French Navy ships. Their specialty is design of nuclear submarines and aircraft carriers. Over the last 50 years they have made more than 17 such vessels.

Fig. 5 FLEXBlue in transit and on location.

maintenance crew when needed. Each module is capable of producing from 50 to 250 MWe using light water reactor technology. An artist rendering of the plant is shown below (Fig. 5).

These modules are roughly 150 m long with a 14 m diameter. The reference module is 160 MWe Pressurized Water Reactor with two steam generators and four canned rotor main coolant pumps. These plants can be linked to provide more power to onshore facilities. They can be anchored in 50–100 m of water a few kilometers from shore. A preliminary safety analysis was performed on this design by DCNS (Haratyk and Gourmel, 2015) which demonstrates that all safety functions can be passively operated without operator actions or electrical power.

There are several goals of this design, the most significant of which is to avoid public objections from placing these plants on land near people while also having the ability to site plants in areas that have high energy demand and where land is scarce or unsuitable for nuclear construction due to the presence of natural or manmade hazards such as other industrial facilities. The subsea location also provides additional safety benefit for having essentially an infinite source of cooling water in the event of an accident. It would be less prone to terrorist attacks. As in other floating reactor concepts, the advantage of factory manufacture, mass production and no major civil engineering structures or massive containments should lower capital costs.

This small modular reactor is designed for a 40 months operating cycle after which it is removed and transported back to a central base for refueling. In its place, another previously refueled module is transported to the site to maintain power capability. It is expected that every 10 years the modules are shipped back for major maintenance. What is interesting in this design is that the reactors are remotely operated.

Korea—BANDI

South Korea has recently signed a memorandum of understanding with South Korea's KEPCO Engineering & Construction Company and Daewoo Shipbuilding & Marine Engineering to develop floating nuclear plants (World Nuclear News, 2020) Korea is a likely candidate for such plants due to their unavailability of suitable shore based sites for new construction. Shown below is an artist rendering of their proposed plant (Fig. 6).

These companies hope to leverage their experience in nuclear reactor design and ship building to construct a floating small modular reactor. Kepco has been working on BANDI-60, a small modular reactor SMR since 2016. This reactor is a 60 MWe reactor which they call a "block" type pressurized water reactor since they have eliminated main coolant pipes in an effort to avoid large break loss of cooled accidents. (Kim et al., 2019) Another unique innovation is to eliminate the use of soluble boron for reactor control replacing it with an in-vessel control rod drive mechanism and top mounted core instrumentation.

The target market for the BANDI 60 is to provide power and heat to remote communities and water desalinization with the additional goal of supporting the variability of renewables on the grid.

China

China has two competing floating nuclear plant designs underway to provide power in the South China Sea to support offshore oil and gas operations. They also have recently been building islands which will require power (Lempriere, 2018). Two companies are developing small pressurized water reactors based on their land based designs. The Nuclear Power Institute of China (NPIC) which is a subsidiary of the China National Nuclear Corporation (CNNC) is developing the ACP100 S which is to be a marine version of the ACP-100 (CNNC to Develop Floating Reactor, 2016). While the details are not known due to secrecy concerns, it appears that the reactors are capable of producing 310 MWt of heat and 100 MWe of power. It has 57 fuel assemblies 2.15 m tall using integral steam generators much like US versions of similar integral nuclear plants.

An artist rendering of this plant is shown below. It is not clear whether this is simply a barge or a motorized ship which contains the reactor (Fig. 7).

Fig. 6 Korean BANDI floating nuclear plant.

Fig. 7 Nuclear Power Institute of China's Floating Nuclear Plant. <https://www.world-nuclear-news.org/Articles/CNNC-to-construct-prototype-floating-plant>.

The second floating nuclear plant is being developed by China General Nuclear Power Group (CGN) is a 200 MWt/60 MWe pressurized light water reactor (CGN to Build Floating Reactor, 2016). It's based on the ACPR50S design employing 37 fuel assemblies providing steam using two primary coolant loops feeding 4 steam generators. CGN has signed an agreement with China National Offshore Oil Corporation.

An artist rendering of the CGN floating plant is shown below (Fig. 8):

The present status of these projects is unknown.

Offshore floating nuclear plant (MIT)

Another interesting concept being developed by researchers at MIT is the Offshore Floating Nuclear Plant (OFNP) which builds on successful offshore oil rig platforms. The MIT team designing the OFNP is made up of seasoned marine industry companies familiar with ship construction and undersea operations. The MIT team has consulted with Newport News Shipbuilding, a US builder of nuclear submarines and air craft carriers, and Sevan Marine, a Norwegian designer of offshore floating oil storage barges. The fundamental idea is similar to other floating designs but on a much larger scale in that a full size 1100 MWe pressurized water reactor could be installed in one of the modules rather than the smaller 60 MWe plants currently being proposed by others (Buongiorno et al., 2016). Other options do include smaller reactors in the 300 MWe such as those small modular reactors being considered by some utilities and countries to meet their specific needs. What is unique in their concept is that the floating platform can be designed to hold any nuclear plant design. Shown on the figure below is a typical rendering of their plant (Fig. 9).

The proposal is to install the reactor in a floating platform similar to that designed by the Sevan Corporation (Sevan Floating Production Storage and Offloading, 2020) for their Floating Production Storage and Offloading platforms (Wikipedia, 2020,c).

Fig. 8 China General Nuclear (CGN) Floating Nuclear Plant. <https://www.world-nuclear-news.org/Articles/CGN-to-build-floating-reactor>.

Fig. 9 MIT Offshore Nuclear Plant. Buongiorno J, Jurewicz J, Golay M and Todreas N (2016) The offshore floating nuclear plant concept. *Nuclear Technology* 194: 1–14.

These platforms are built in shipyards and are routinely used in the offshore oil industry. One of the unique advantages of this system is that they are extremely stable platforms for nuclear plants able to endure storms, offshore tsunamis and earthquakes (Fig. 10).

The MIT design calls for building these platforms in a shipyard and installing proven licensed pressured water reactors or other reactor types into the vessel in a controlled environment. The platform would then be shipped or towed to a location 20 km offshore and anchored at the location from which 345 KV AC cables would be used to transport the power to a land location for distribution (Fig. 11).

The uniqueness of this design is that it can be moored virtually anywhere in relatively deep water (100 m) which would address earthquake, hurricane or tsunami risks. The plant would be self-sufficient in that refueling would occur at sea and when its useful life of 60 or so years is completed, it could be floated back to the shipyard for decommissioning, much like the US fleet of nuclear ships and submarines. The figure below shows what such a nuclear plant might look like being transported to an offshore site (Fig. 12).

The design team has developed the concept to allow for a visual of the layout which is shown below.

The design calls for placing all safety critical equipment in water tight compartments. As in oil platforms, the operating staff will have living quarters with monthly shift changes. Minor maintenance would be conducted at sea with a major outage every 10 years at which time the platform would be towed back to a central maintenance facility. Refueling would be conducted at sea every 12–48 months since an on-site spent fuel pool would be located on the platform capable of holding all the spent fuel for the 40 year expected life of the facility. To supply freshwater, the plant would also have a desalinization plant (Fig. 13).

Fig. 10 Sevan offshore oil storage platform being shipped. <https://sevanssp.com/sevan-fps0/#>.

Fig. 11 Rendering of anchorage system of offshore floating nuclear plant. <https://sevanssp.com/sevan-electrified-fps0/>.

The feasibility of this concept is best demonstrated what is already being deployed worldwide using the Sevan design. Their floating platforms for oil storage and operation are 110 m tall, 90 m in diameter with a draft of 30.5 m. The expectation is that existing reactor designs such as the AP-1000 can be inserted into these platforms in a shipyard (Fig. 14).

As with other floating nuclear plants, the safety is ensured by the use of the ocean as the ultimate heat sink to remove decay heat in the event of an accident. Numerous safety studies have been performed on this design showing not only the feasibility of the anchoring system during storms but also using conventional safety analysis (Zhang et al., 2018), (Strother, 2015). The defense in depth principles are shown in the figure below. What is noticeably different from land based plants is the lack of a 3–4 ft thick reinforced concrete structure needed for loss of coolant accident pressure control and security against aircraft impact. This is a significant savings in capital cost (Fig. 15).

Seaborg floating nuclear plant—Denmark

A surprising new entrant into the floating nuclear plant market comes from Denmark, a historically anti-nuclear country. What is unique about their design is that instead of using light water reactors, they have chosen a molten salt fueled reactor of 250 MWth/100 MWe with barge capacities ranging from 100 to 600 MWe. (Jaspen, 2020) Molten salt reactors (Ignatiev, 2021) use a fluoride salt to dissolve thorium fuel so that the core is essentially circulating liquid fuel. Seaborg's design is unique in that the core consists

Fig. 12 Artist rendering of OFNP being transported. Buongiorno J, Jurewicz J, Golay M and Todreas N (2016) The offshore floating nuclear plant concept. *Nuclear Technology* 194: 1–14.

of a collection of tubes through which the fuel flows surrounded by a molten salt moderator likely sodium hydroxide (Lovschall-Jensen, 2019) (Fig. 16).

These are higher temperature reactors that operate at 600 °C but at atmospheric pressure which is an advantage. Few such reactors (especially thorium) have operated especially on a commercial scale which suggests a great deal of

development will be required. They might start with a uranium core to allow for earlier deployment. The challenge is dealing with the corrosion due to the molten salts on metals. The expectation that the Seaborg will have an operating cycle of 12 years before refueling.

Shown on Fig. 17 below is an artist rendering of the Seaborg CMSR in an arctic location providing heat and power to such a remote location. This concept is very early in development funded by private investors.

Other concepts

There are other floating nuclear plant concepts that are being investigated mostly by Russia based on their experience with marine propulsion systems (International Atomic Energy Agency, 2013). The most notable is a lead/lead bismuth cooled fast reactor which was used in early Russian Alpha class submarines however not very successfully. All have been retired. The SVBR 100 was a joint venture with AKME Engineering. The 100 MWe plant was to have an operating cycle of 7–8 years before refueling with uranium dioxide, mixed oxide or nitride fuel. In all, the Russians have about 80 reactor years of experience with these reactors (Fig. 18).

Another Russian concept is the ABV-6M which has a power rating of 8 MWe (Bakhmetyev et al., 2015) This reactor is being designed under the leadership of OKBM with the goal of autonomous operation. It is an integral pressurized water reactor with steam generators in the reactor vessel designed for a fuel cycle of 10–12 years without refueling. It is to be barge mounted with twin units (Fig. 19).

Proliferation and security concerns

A concern about deployment of many such plants around the world relate to the risk of nuclear proliferation and security. Depending on the operational model, these floating plants could be operated as a fleet by responsible companies or nations ensuring not only the safety of operation but the ability to keep the spent nuclear fuel in a secure state. Commercial nuclear plants use low enriched uranium, 4–5%, which make it impossible for a nuclear weapon which needs over 93%. The spent nuclear fuel, once its useful life for power production is over, does contain a mix of radioactive materials including plutonium 239 which is fissile.

Fig. 18 Russian SVBR floating reactor barge concept. International Atomic Energy Agency (2013) *Legal and Institutional Issues of Transportable Nuclear Power Plants: A Preliminary Study*. Vienna: IAEA.

Fig. 19 ABV-6M Russian design. (Bakhmetyev A, Bylov I, Lepekhin A and Fadeev Y (2015) *Small Modular Reactors Engineering Solutions for Safety Provisions*. OECD/NEA Workshop on Innovations in Water Cooled Technologies: Issy-les-Moulineaux.)

However, in order to obtain sufficient quantities for a weapon, a complex chemical reprocessing process is required which would be easily detected should some nation decide to pursue a nuclear weapon via plutonium extraction from irradiated fuel. In addition, the International Atomic Energy Agency which inspects international nuclear facilities for proliferation concerns would also apply their protocols to these floating plants. Thus, from a proliferation point of view, commercial nuclear plants themselves are quite proliferation resistant.

What makes the floating nuclear plants attractive from a non-proliferation perspective is that nations do not need to have uranium enrichment plants that can be a direct path to making high enriched uranium nor would they need reprocessing plants, and still have the benefits of clean nuclear energy. The best model for use of floating nuclear plants from a non-proliferation perspective is that the supplier of the plants would provide all services from operation, spent fuel storage and disposal at their (Ignatiev, 2020) central facility (Mckinzie, 2021). Some of the floating nuclear plants have life time storage of spent fuel capability while others require the transportation of the barge back to the central facility after a number of years of operation. During transportation of the barges, there is some risk of interception but given the security protocols that would be in place, the likelihood of a successful

theft of the spent fuel is very low. At present, Sweden, France, England, Japan, and the United States have shipped spent fuel and fresh fuel safely by sea for over 40 years.

It is expected that some nation or international consortium could possibly provide all such fuel cycle services and waste disposal solutions (Hore-Lacy, 2020). Thus, under such a model, these plants provide a non-proliferation alternative for the use of nuclear energy which would avoid the need for enrichment and reprocessing plants.

From a security perspective, clearly offshore locations make access to the plant much more difficult. As an example, security has been considered in the MIT design as shown the by figure below which establishes several security zones for access and monitoring. As in all nuclear plants, a security team working from defensive positions would be stationed on the platform to monitor and repel any intrusion attempt (Fig. 20).

Objections and disadvantages

The political pressure group, Greenpeace, has objected to the use of the Akademik Lomonosov in Siberia for several reasons beyond their general dislike of nuclear energy despite the reluctant admission that it will help reduce carbon emissions in these remote communities. They argue that due to its remote location, it will be hard to get qualified workers to staff the facility and respond to emergencies should it be needed (Cholteeva, 2020). They are concerned about the barge sinking and that spent fuel will remain on the barge for years before being removed causing a potential pollution problem. They are also concerned about the transportation of the barges to and from their moored location. The designs, such as the MIT design, have double hulls to avoid such problems and others would be shipped on other vessels such as the FLEXBlue design. While legitimate concerns, they are recognized in design and operation.

While the advantages are many, transporting such large structures over long distances (shipyards in the Southeast Asia) can be a challenge especially with changing weather conditions for such long journeys. Transporting unfueled reactors is not the concern but once returned to the factory shipyard for refueling, the risks do increase.

Licensing and regulatory challenges

As in any nuclear enterprise, regulatory compliance can be a challenge especially in the case of a floating nuclear plant traveling through international and national waters. In the case of the proposed Atlantic Nuclear Generating Station, the Nuclear Regulatory Commission not only approved the manufacturing license, it also approved the siting and shipment of the barge to a location off the New Jersey coast. This approval and process was a good precedent for a regulatory approach to a national installation. Russian regulatory authorities approved the design, construction and siting of the Akademik Lomonosov in Pevek.

Licensing barges or floating offshore platforms containing nuclear reactors would not only have to comply with nuclear safety regulations by the host country but also international rules for shipping nuclear materials. While the nuclear navies of the world are not internationally regulated for transport, at present there are no legally binding international conventions that address the floating nuclear plant options being considered. One example is how should a fueled reactor which would be tested prior to transport is to be treated under international conventions such as that expected for FLEXBlue. There have been four commercial nuclear powered cargo /passenger ships built to date, only one of which is still operating—Sevmorput (Russia) (Wikipedia, 2020a,b). Perhaps the most famous commercial ship was the NS Savannah built in 1959 by President Eisenhower under the Atoms for Peace Program. This ship visited 45 countries, 32 domestic US ports traveling over 450,000 miles. She was placed in active passenger and cargo service from 1962 until 1971 when she was retired and now is

Fig. 20 Security Considerations (nm stand for nautical miles). Buongiorno J, Jurewicz J, Golay M and Todreas N (2016) The offshore floating nuclear plant concept. *Nuclear Technology* 194; 1–14.

Fig. 21 NS Savannah Nuclear Powered Commercial Ship. Wikipedia (2020a) NS Savannah. Retrieved From NS Savannah: https://en.wikipedia.org/wiki/NS_Savannah.

a National Historic site museum in Maryland. During her visits to ports around the world she hosted over 1.4 million people for tours. The Savannah experience shows that shipping commercial nuclear power plant is possible under international regulations and conventions (Fig. 21).

Shipping an unfueled reactor is much simpler since shipments of all parts of the reactor are routinely done as are shipments of fresh unirradiated fuel such as was the case with the Russian Akademik Lomonosov. However once the fuel is irradiated after operation, all would be subject to national and international regulations, some of which have not yet been agreed to. While shipments of irradiated fuel are also routinely done by ship, it should not be a more difficult challenge to gain such approvals for transit through waters of other countries. The International Atomic Energy Agency, among others, have studied this issue reviewing a number of options (International Atomic Energy Agency, 2013).

Countries accepting such floating nuclear plants must either accept the regulatory review and approval of the supplier nation or develop their own for floating plants within their territorial limits. For developing nations, this is seen as a positive feature since while they need to have a regulatory oversight function, they do not need a formal regulatory system needed to license such a facility.

Fig. 22 Summary of floating nuclear plant designs.

It is unclear how floating nuclear plants would be treated if moored outside a nation's territorial limits in international waters. International treaties covering this option would need to be negotiated.

International liability laws also need to be developed such that insurance can be provided to the developer and host country in the event of an accident during operation or during transport. These agreements need to be in place prior to any international commerce of such technologies. Land based reactors sold to countries have forms of liability protection which seem to be possible for floating plants but not yet agreed to.

Summary

Fig. 18 below summarizes the various offshore power systems being considered today. As can be seen there are many choices each with its unique advantages given the location, electricity needs and siting considerations. Other applications include moored barges protected by breakwater such as the Atlantic Offshore plant or barges resting on the seabed. The goal of all these concepts is to avoid local siting problems and challenges, standardize construction and increase efficiency and reduce costs by building in central shipyards for world wide deployment. The additional safety advantage of the sea provides an assured supply of cooling water minimizing accidental risks. Regulatory, legal and institutional challenges remain for international use of floating nuclear plants but are not seen as insurmountable (Fig. 22).

Floating nuclear plants offer the international community a safe and potentially economical source of clean energy using existing technology already deployed in both the nuclear and marine industries. Additionally, there are significant non-proliferation advantages to floating nuclear plants for many nations since they would not need a nuclear fuel cycle infrastructure. More detailed engineering is needed to implement some of the concepts but the challenges are manageable. The Russians with their first barge mounted plant and many nuclear navies around the world have shown the feasibility of offshore floating nuclear plants.

Definition of microreactors and what role they have

Microreactors are generally understood to be the smallest fission reactor category, although specific definitions vary significantly. The term tends to be used more in certain parts of the world, especially the United States of America, while some parts of the world tend to consider microreactors as a subcategory of small modular reactors, occasionally termed “very small modular reactors (vSMRs)” (<https://www.world-nuclear.org/information-library/nuclear-fuel-cycle/nuclear-power-reactors/small-nuclear-power-reactors.aspx>). The International Atomic Energy Agency (IAEA), for instance, does not define a separate subcategory of SMRs (<https://www.iaea.org/topics/small-modular-reactors>). The interest in microreactors has grown globally with the concurrent interest in low greenhouse gas emission energy, growing global energy use, the expansion of microgrids, and the need for reliable energy supplies for critical facilities like military bases and hospitals.

As the smallest reactor class, the definition of a microreactor usually involves some kind of upper limit to the size or capacity of a reactor in order to be defined as a microreactor. The definition of microreactor has ranged from below 10 MW-electric (MWe), to below 30 MWe/100 MW-thermal (MWth) to below 50 MW of unspecified output as shown in **Table 1**. A possible reason for this variety of definitions is that microreactors will be serving different markets than large-scale nuclear reactors.

Table 1 Definitions of microreactor power ranges.

Entity	Thermal power	Electrical power	Notes
US Department of Energy (https://www.energy.gov/ne/articles/what-nuclear-microreactor)	< 20 MW		Also has described characteristics not related to power level
US Department of Defense (https://www.nei.org/CorporateSite/media/filefolder/resources/reports-and-briefs/Road-map-micro-reactors-department-defense-201810.pdf)		< 10 MW	
US Congress in the National Defense Authorization Act (https://www.nei.org/news/2018/congress-directs-doe-study-of-micro-reactor-deploy)			< 50 MW of “power production”
UK Department of Energy and Climate Change (https://assets.publishing.service.gov.uk/government/uploads/system/uploads/attachment_data/file/787411/Market_and_Technical_Assessment_of_Micro_Nuclear_Reactors.pdf)	< 100 MW	< 30 MW	

Historically, the primary output of commercial nuclear reactors has been electricity, and reactors were commonly rated by the electrical output. However, end users for microreactors may be more interested in direct heating, cogeneration of electricity and steam, or use of industrial process heat. This means that a discussion of MWth is involved more frequently in the definition of microreactors as opposed to more traditionally-sized larger plants. In general, microreactors are defined by their output, although some definitions have attempted to include other attributes, such as operational characteristics. Because the market demand and supply are still evolving, it is to be expected that there is no single clear definition which has emerged. Ultimately, at the time of writing, the most typical definition of microreactors is based on producing on the order of single-digit megawatt electrical output, i.e., less than 10 MWe although up to 50 MWe may be considered.

On occasion, radioisotope thermoelectric generators (RTGs) may be considered a subtype of microreactors. These would not be a “reactor” in a literal sense because they do not sustain a fission reaction in order to produce heat and thereby electrical power. RTGs utilize heat from isotope decay to generate power (Bennett, 2021a,b) and usually produce tens to hundreds of watts of electrical power. However, this article will focus on fission microreactors.

Near term applications

Microreactors, because of their size and technology flexibility, have a range of potential near term applications. Many research and test reactors historically have had power capacities within the range of microreactors, and there are currently about 31 such reactors in operation in the United States alone (<https://www.nrc.gov/reactors/operating/map-nonpower-reactors.html>). Microreactors also have a history of use for power and cogeneration around the world, and there are a few currently operating and currently under construction for various applications as shown in Table 2. In fact, the first privately owned and operated reactor to commercially provide power on the US grid was a 5 MWe microreactor, the Vallecitos BWR which operated in California between 1957 and 1963

Table 2 Current and near-term applications of microreactors (reactors under 50 MWe, not including research-only reactors which do not produce electrical power).

Reactor	Status	Application	Location	Type	Size
EGP-6 #2 (http://rosenergoatom.ru/stations_projects/sayt-bilibinskoy-aes/)	Currently operating	Cogeneration power	Bilibino, Siberia	Graphite moderated boiling water reactor (BWR)	12 MWe

(<https://www.asme.org/wwwasmeorg/media/resourcefiles/aboutasme/who%20we%20are/engineering%20history/landmarks/128-vallecitos-boiling-water-reactor-1957.pdf>).

Because there is increased interest worldwide, there are also a number of commercial microreactor designs in development. For these newer commercial offerings, it is expected that early units will have higher costs than some mainline markets within the United States, and so the near term applications are likely to be locations where either the cost for current electricity supply is high, the logistics for electricity supply is precarious, or the need for reliable power is significant; or a combination of all three. Longer term, microreactors have the potential to achieve cost competitiveness with mainline grid prices throughout the world.

Microgrids are a natural application for microreactors. This may include artificially created microgrids, i.e., where an end user may be connected to a large grid but prefers its own supply, or where an end user purchases a certain level of service from a large provider that exceeds the reliability or guarantee of the larger grid as a whole. Examples of microgrids which represent near term applications for microreactors include remote residential, commercial, or industrial sites, resorts, campuses, or military bases.

Specific types of residential, commercial, industrial and military sites that may find particular benefit by the low emissions, reliability, and resilience of this power source include emergency power supply to large nuclear power plants, some data centers, large hospitals, mining and other resource production sites, military bases, island communities, and communities in far northern or southern areas of the world with few energy options.

Emission-free power in the far north

Communities in far northern areas around the world do not have ready access to energy. In many areas, transportation of fuel may only be possible in certain times of the year. Due to the northern geography, solar power may be ineffective for significant portions of the year. Similarly, hydropower resources may not be available in times of the year. There is a history of use of microreactors in northern areas in Siberia in Russia, where four reactors producing approximately 12 MWe have been operating since the 1970s. These reactors also cogenerated process heat. Other northern areas, such as the northern territories of Canada as well as the US state of Alaska, have explored the use of microreactors. Current remote microgrid fossil fuel capacity installed in Canada is about 750 MWe (<https://atlas.gc.ca/rced-bdece/en/index.html>), and in Alaska there is approximately 150 MWe of installed capacity (<https://www.eia.gov/state/?sid=AK>).

Emergency power backup to existing plants

There has been interest to utilize microreactors as emergency power backup for existing large nuclear plants. Licensing a very small additional reactor on a site already prepared for a large reactor should present a relatively manageable challenge, while the benefit would allow for the site to have a robust source of power available to the larger reactor should it be needed. There is interest in improving the startup time and reliability for emergency diesel generators for large plants, but if a power source is already onsite and already powered up, this would be of use for the plant safety and reliability as a whole.

Resilient power for defense applications

Another particular application which has received attention particularly in the United States is the use of microreactors to improve energy independence and resilience of military bases and other critical assets. Both the United States and Russia have had microreactors for defense purposes built and tested or operated in the mid-20th century, although the interest has been renewed in recent years with modern technologies. The US Department of Defense spends billions of dollars a year on energy. Ninety percent of US military installations have an average annual energy use that can be met by an installed capacity of nuclear power of 40 MWe or less (<https://www.nei.org/CorporateSite/media/filefolder/resources/reports-and-briefs/Road-map-micro-reactors-department-defense-201810.pdf>).

Global developing microgrids and new markets

Most broadly, microreactors could present a valuable supply of emission-free and reliable power to any microgrid. Worldwide, there is more than 22,500 MW of installed remote power sources utilizing fossil fuels, and more than two-thirds of these are located in developing and emerging countries (<https://reiner-lemoine-institut.de/en/global-analysis-of-the-utilization-of-diesel-generators-for-remote-power-supply/>). Another estimate puts the global market demand at 1000 GW (i.e., 1,000,000 MWe) (<https://www.esi-africa.com/news/hybrid-micro-grids-beginning-of-the-end-for-diesel-gensets/>). This global market size, as well as the market need, is only expected to grow. The specific fraction of this need which could be met by microreactors could depend on a number of factors. According to the UK Department of Energy & Climate Change, there will be a potential global accessible market for microreactors of up to 2850 MWe by 2030 (https://assets.publishing.service.gov.uk/government/uploads/system/uploads/attachment_data/file/787411/Market_and_Technical_Assessment_of_Micro_Nuclear_Reactors.pdf). That said, there are areas of the world where markets have not even been allowed to develop because neither fossils nor renewables may be practical. It is in these emerging and niche markets that microreactors may create wholly new means to supply energy to markets that are not yet in existence.

Unique benefits and risks of microreactors

While microreactors offer many of the same benefits and risks as traditional large-scale nuclear reactors, their tiny size and simplified engineering also provide unique benefits as well as risks. Many of the benefits will depend on the specific reactor technology and fuel cycle, although some are universal to such small designs. Similarly, inherent risks are dependent on the deployment model and safety features of each design.

Benefits

The main benefit of microreactors is lower overall cost. While the cost to generate electricity may be higher than a large light-water reactor per kWh, the total cost is low enough to open up new markets. For example, traditional nuclear power plants could only be owned and operated by the largest utilities in the United States, and typically operated by state-owned or state-supported utilities outside of the United States. If total project costs for a microreactor plant are in the tens of millions range, they could be purchased by small utilities, rural electric coops, and municipal utilities. In addition, they could be financed by private investment instead of relying on federal loan guarantees, investment tax credits, or other state support. Similarly, shorter and predictable construction duration is another expected benefit of microreactors over large-scale nuclear power plants. After the first demonstration projects, customers should be able to order a microreactor with confidence that it will be delivered on a specified time range, measured in tens of months not tens of years. Beyond more predictable construction schedules, factory-fabricated reactors should also come with fixed, predictable costs for customers.

Most microreactors are non-LWRs that come with a range of unique safety benefits. Yet, the very small size of microreactors allows further inherent safety due to simplified engineering and a reliance on physics rather than engineered safety systems. Depending on the design, microreactors are able to eliminate many of the redundant and active safety systems, relying more on natural physical properties to maintain reactor control. This not only lowers costs, but also results in reactors with reduced risk of accidents, and minimized need for operator intervention in the case of an accident. Additionally, the reduced risk allows for a much smaller Emergency Planning Zones—the area around a nuclear power plant where owners must prepare emergency evacuation plans in the rare event of an accident—meaning that microreactors could be located closer to populations centers where the electricity is needed.

Both the small size and non-LWR designs also allow microreactors to significantly reduce or even eliminate their water consumption especially those that use direct cycle gas turbines. This has economic, safety, and environmental benefits. On the economic side, customers do not have to worry about securing access to a reliable water supply for a potential power plant, which also opens up the market to inland and arid regions. On the safety side, operators do not have to worry about supplying consistent water to cool the reactor in the event of an accident. And on the environmental side, these designs reduce the consumption of fresh water from ecosystems, as well as reduce thermal pollution from warm water returning to aquatic ecosystems.

While the first commercial microreactor projects will likely be off-grid locations, many currently on-grid communities are looking to take ownership of their power generation. This movement towards distributed and decentralized power generation is normally associated with renewable energy, but declining costs of microreactors in the longer term could open up this potential market. Microreactors would offer these communities reliable, low-carbon electricity at a long-term fixed rate.

Lastly, large-scale nuclear power is valued on the power grid for its reliability. Microreactors would open up this valuable attribute to smaller off-grid and microgrid markets. For example, many US defense installations require back-up diesel generators to maintain critical operation in the event of a failure of the central grid. Microreactors could provide consistent power for mission critical operations or the entire installation, depending on size. Additionally, nuclear can provide islanding and black start capabilities, allowing the grid to be isolated during an emergency event or turned back on after a power outage. Currently, these services are only available from fossil fueled generators.

Risks

The specific risks from nuclear power are well-understood, and microreactors do not seem to come with many unique risks. However, most microreactor vendors expect lower staffing levels than required for regulated facilities which are hundreds of times larger. And many developers tout use of automatic controls for reactor operation. Some have proposed use of remote operation. Such capabilities provide many economic benefits, but some capabilities pose new risks. For instance, remote operation will create a cyber-security risk which is not present in existing LWRs which utilize analog controls and are not connected to the internet or a network offsite. Since many of the regulations governing existing nuclear power plant safety and physical security are based on requiring safety systems to actively function to ensure safety, and for well-trained staff to initiate those active systems, designs will need to show that passive or inherent safety or active controls have lower levels of error than human error, if the controls affect safety or security of the plant. This challenge may be straightforward, but may make some potential customers and regulators wary.

Some proposed uses of microreactors include requirements for transportability and minimizing weight which allows for minimal amounts of shielding; for instance, the recent US DoD solicitation of information targeted designs weighing less than 40 tons, able to operate for at least 3 years, in the range of 1–10 MW ([FedConnect, n.d.](#)). This use capability would have new risks or challenges regarding ensuring dose levels remain below safe limits for those in forward-operating areas.

Current development efforts of microreactors

While the concept of microreactors is not new, there is renewed interest in commercializing such designs that has led to a relative boom in concepts. In addition, new US federal programs aimed at advanced nuclear technologies may be accelerating commercialization of new nuclear technologies. Among the list of microreactors put forward, many are scaled-down versions of larger reactors the vendor ultimately hopes to build, meaning the microreactor could be a commercial demonstration of a new technology that is the first step toward licensing of a larger advanced reactor design. Yet other vendors are specifically developing a microreactor as their final product. While Russia and China are also developing microreactor concepts, their focus for advanced reactors appears to be at larger scales and thus are excluded from the following descriptions. **Table 3** provides a summary of the most mature microreactor concepts for US and Canadian markets.

All vendors are US-based unless otherwise noted. Reactor technology acronyms: *HTGR*, high-temperature gas-cooled reactor; *LFR*, lead-cooled fast reactor; *HPR*, heat pipe reactor; *LWR*, light-water reactor. Fuel terminology: Low-enriched uranium (LEU) less than 5% U235, high-assay low-enriched uranium (HALEU) is enriched to 5%–20%.

Looking at the microreactors under development in **Table 3**, all of the designs are non-LWR with the exception of NuScale. All developers anticipate using HALEU, with the exception of NuScale and General Atomics. Gas-cooled reactors may be the most common in part because the US Department of Defense laid out a requirement for a transportable reactor to utilize TRISO fuel, and many developers are in competition for this solicitation. There are also a few molten salt designs (either in the primary or secondary cooling loop). There are two sodium-cooled designs and one lead-cooled design, which are likely taking advantage of experience with sodium-cooled designs globally. Many developers are planning to use TRISO fuel, which has some history of commercial-scale fabrication. Several vendors claim load-following capabilities and autonomous operation.

DOE's Gateway for Accelerated Innovation in Nuclear (GAIN) program began offering vouchers in 2016 which allow for payments directly from DOE to the national laboratories, and enable advanced nuclear developers to direct research and access experimental facilities and expertise at national laboratories (<https://gain.inl.gov/SitePages/Nuclear%20Energy%20Vouchers.aspx>). Several microreactor developers have been awarded these vouchers, detailed below. DOE has also awarded small grants for specific research and development projects to several advanced reactor developers.

On the demonstration side, there are several programs in the United States and Canada helping to accelerate first-of-a-kind (FOAK) demonstrations. In the United States, there have been several studies and a recent request for information from DOE for a pilot program to deploy microreactors at federal sites, such as DoD and national laboratories. In 2016, Canadian Nuclear Laboratories put out an invitation for SMR developers to submit proposals to build a demonstration reactor at their Chalk River site, with the goal of commissioning before 2026. This has spurred several companies to initiate the pre-licensing, four-stage vendor design review with CNL (CNL, n.d.).

Details on specific microreactor concepts in development

What follows are more details on where each vendor stands on commercialization of their microreactor concept, including specific funding and licensing progress. Companies are in alphabetical order.

General atomics

General Atomics has a long history with building very small reactors as one of the leading vendors for research reactors globally. Their energy multiplier module is a 4–10 MWe high-temperature gas-cooled reactor that has a unique breed and burn configuration (Qvist, 2021), allowing it to run on low-enriched uranium (LEU) while also having a long core lifetime (30 years). They claim the reactor can load-follow, operate mostly autonomously, and be transported in a standard shipping container (<http://www.ga.com/advanced-reactors>).

As GA's design relies on silica carbide fuel, much of their development work is focused on qualifying this novel fuel. In 2018, they received \$2.2 million to test a new method of qualifying fuels that could reduce the cost and schedule. They received an

Table 3 A summary of microreactor concepts farthest along in development.

Vendor	Technology	Capacity	Core lifetime (years)	Fuel type and enrichment
General Atomics	HTGR	4–10 MWe	30	1% U235, silica carbide fuel rods
HolosGen	HTGR	13 MWe	12–20	Up to 15% HALEU
LeadCold (Sweden)	LFR	3 MWe	10–30	19.9% UO ₂
NuScale	HPR	1–10 MWe	> 10	HALEU
Oklo	HPR	1.5 MWe	< 20	Low-enriched metal fuel
Ultra Safe	HTGR	5 MWe	20	9%–12% TRISO
Urenco (UK-Dutch-German)	HTGR	10 MWth	5–10	TRISO (mix of UO ₂ and ThO ₂)
Westinghouse Evinci	HPR	0.2–15 MWe	> 10	HALEU oxide
X-energy	HTGR pebble bed	10 MWth	~ 10	HALEU TRISO

additional \$0.4 million to engage with the NRC on a pre-application license review of their carbide fuel (<https://www.energy.gov/articles/secretary-energy-rick-perry-announces-60-million-us-industry-awards-support-advanced>) (Fig. 1).

HolosGen

Based on technology originally developed for airborne reactors at Los Alamos, HolosGen is developing a gas-cooled fully mobile microreactor. The design is scalable from 3 to 13 MWe, cooled by Helium or Carbon Dioxide, with fuel enriched up to 15% U235. The design has an integrated balance-of-plant, making the entire power plant fit inside a standard shipping container (<http://www.holosgen.com/>) (Fig. 2).

LeadCold nuclear

Sweden-based LeadCold is designing a 3–10 MWe lead-cooled fast reactor for remote arctic applications. The fuel is uranium oxide enriched to 19.9%, allowing a core lifetime of 10–30 years (<https://www.leadcold.com/sealer.html>). LeadCold has submitted a 55 MWe reactor of similar design for review to the UK's Department for Business, Energy & Industrial Strategy. They have also submitted an Expression of Interest to Canadian Nuclear Laboratories' invitation for vendors to build and operate an SMR at their site. They began Phase 1 of pre-licensing vendor design review in January 2017 with the Canadian Nuclear Safety Commission, but their review is currently on hold at their request (<http://nuclearsafety.gc.ca/eng/reactors/power-plants/pre-licensing-vendor-design-review/index.cfm>) (Fig. 3).

NuScale power

NuScale, the clear front-runner for SMR light-water reactors in the United States for their 50 MWe SMR design, is also developing a heat pipe reactor under 10 MWe that will use TRISO fuel. This new design will have a smaller footprint and longer core lifetime than their 50 MW LWR reactor, but further details are not publicly available (Fig. 4).

Fig. 3 Mockup of LeadCold's SEALER-Arctic reactor. Photo Credit: LeadCold, <https://www.leadcold.com/sealer.html>.

Oklo

Oklo is a company based in California, and they have long been a front-runner in micro-scale advanced fission development. In November of 2019, Oklo launched their first product, the Aurora powerhouse. In December of 2019, Oklo received a site use permit to from the US Department of Energy to build their microreactor at the Idaho National Laboratory (INL) ([Business Wire, Oklo Inc., 2019](#)). In February of 2020, Oklo announced that INL selected Oklo to demonstrate fuel reuse in the Aurora powerhouse. In March of 2020, Oklo submitted a Combined License Application to the US Nuclear Regulatory Commission, making them the first non-LWR design to submit such an application ([Bandyk, 2020](#)). The Aurora powerhouse utilizes solar panels and a 1.5 MWe advanced fission battery that relies on heat pipes to minimize moving parts. They are looking to deploy the Aurora powerhouse in off-grid communities that currently rely on diesel, particularly in Alaska ([Fig. 5](#)).

Ultra safe nuclear corporation

Ultra Safe Nuclear is the front-runner in Canada's pre-licensing review process. Their design is gas-cooled in the primary loop, but the secondary cooling loop is molten salt, allowing more flexibility in thermal storage (<https://usnc.com/MMR.html>). Ultra Safe began pre-licensing vendor design review with the Canadian Nuclear Safety Commission in December 2016 and was the first—and so far only—SMR vendor to begin Phase 3 of the review (<http://nuclearsafety.gc.ca/eng/reactors/power-plants/pre-licensing-vendor-design-review/index.cfm>). Ultra Safe has also received \$400–\$800 thousand annually since 2016 from the Small Business Innovation Research program, mostly for research on space-based nuclear thermal propulsion systems (<https://www.sbir.gov/sbc/ultra-safe-nuclear-corporation>) ([Fig. 6](#)).

Urenco

Urenco is one of the largest uranium enrichment companies, supplying about 30% of the world's enrichment services. In 2008 they announced a challenge to develop a microreactor that functioned like a battery for use at remote mining sites. The University of Manchester (UK) and Delft University of Technology (NL) collaborated to develop the winning project which is now called U-battery (<https://www.u-battery.com/>). The U-battery is a 10 MWth high-temperature gas-cooled reactor with a lifetime of 5–10 years. They plan to use TRISO fuel that is a mix of UO_2 and ThO_2 . Urenco has partnered with several large industrial firms to complete and commercialize the design. Urenco submitted their application for Phase 1 of vendor design review to the Canadian Nuclear Safety Commission in February 2017 ([Fig. 7](#)).

Westinghouse

While Westinghouse has many reactor concepts in development, their microreactor is based on the megapower reactor developed at Los Alamos National Labs, which was a scaled-up version of a space-based reactor concept. The design, called eVinci, is radically simplified, relying on heat pipes to minimize moving parts and allow mostly autonomous operation (<http://www>.

Fig. 6 Ultra Safe Nuclear Corporation's reactor concept. <https://usnc.com/MMR.html>.

Fig. 7 Urenco's U-battery design. Photo credit: <https://www.u-battery.com/>.

westinghousenuclear.com/new-plants/evinci-micro-reactor). The design is scalable from 200 kW to 15 MWe with a core lifetime of over 10 years. They are planning to use a HALEU oxide fuel. In 2019, Westinghouse received \$13 million from DOE to prepare the eVinci design for demonstration by 2022 (<https://www.energy.gov/ne/articles/us-department-energy-further-advances-nuclear-energy-technology-through-industry-awards>). Westinghouse contributed another \$15 million toward this effort. In February 2018, Westinghouse submitted their application for Phase 2 of vendor design review to the Canadian Nuclear Safety Commission (<http://nuclearsafety.gc.ca/eng/reactors/power-plants/pre-licensing-vendor-design-review/index.cfm>) (Fig. 8).

X-energy

X-energy is developing a 10 MWth high-temperature, gas-cooled pebble bed reactor. The design will be 10 MWth with a core lifetime of about 10 years. The company has been very focused on scaling up the commercial supply chain of UCO TRISO fuel pebbles (<https://x-energy.com/reactors/>). X-energy began pre-application licensing activities with the NRC in September of 2018 (<https://www.nrc.gov/reactors/new-reactors/advanced/xe-100.html>). DOE granted X-energy \$4.5 million in 2018 to design and license a TRISO fuel fabrication facility. X-energy contributed \$4.5 million of their own to this project (Fig. 9).

Summary

Microreactors have the potential to be a disruptive nuclear technology due to their unique attributes and niche market opportunities. These designs are moving faster through the commercialization process than many anticipated just 5 years ago, and policy may need to play catch up with where the technology is moving. The very small size of microreactors not only reduces the total cost, but

allows for real factory fabrication along with consistent production schedules. The improved safety profiles of such small, non-LWR technologies can also simplify operations and reduce staffing levels on-site.

The lower absolute cost combined with the reliability of nuclear energy could open up new markets for microreactors. These very small reactors could soon be powering off-grid communities at northern latitudes or island cities. Customers that require high-reliability from the power sources—such as military bases, large hospitals, or off-grid mining sites—could also benefit from commercial microreactor technology.

Policy-makers should begin the process of developing supportive policies to accelerate commercialization of these designs, but also level the playing field in the power sector to allow microreactors to compete with fossil fuels and cooperate with renewable energy to expand low-carbon generation.

In December 1942, the Chicago Pile-1 (CP-1) demonstrated the feasibility of self-sustaining nuclear chain-reaction. However, the public realization of the enormous power of nuclear energy was not until the detonation of a nuclear weapon in August 1945. Ever since the dawn of the nuclear age, the potential for peaceful uses of nuclear energy often raised concerns that the potential spread of nuclear weapons would be catalyzed by a civilian nuclear power program. There is also the possibility of theft of fissile material or nuclear technology by non-state entities or terrorists. Though nuclear power reactors and nuclear weapons operate under different conditions, they rely on a similar scientific basis and use similar materials and technologies. This article discusses some of the activities and characteristics related to curtailing and deterring proliferation associated with worldwide deployment of nuclear energy; that is, the non-proliferation aspects of nuclear energy from the perspective of policy, regulation and design.

The early years

Leo Szilard, a Hungarian-German-American physicist and inventor, filed for a patent in England on the concept of neutron-induced nuclear chain reaction in 1933 (granted in 1936) while the mechanism of nuclear fission was not discovered until 1938. In December 1939, Szilard drafted a letter signed by Albert Einstein to President Franklin D. Roosevelt, alerting the President to the potential for a vast amount of power that could be released from a nuclear chain reaction in uranium. The Szilard-Einstein letter prompted the birth of the Manhattan Project that ushered in the nuclear conundrum – the potential for harnessing the power of nuclear energy as a weapon and also as an alternate source of energy. For more information on this topic see [Reed \(2021\)](#).

An early attempt to manage nuclear energy after World War II was suggested in the Report on the International Control of Atomic Energy, written by a committee chaired by Dean Acheson and David Lilienthal in 1946 (aka the Acheson-Lilienthal Report). It proposed methods for the international control of nuclear weapons and the avoidance of future nuclear war. The report also recommended that all fissile material be controlled by an international agency and small amounts would be released to individual nationals for peaceful uses of nuclear energy.

In the United States, the first domestic legislation to control nuclear energy was enacted in the Atomic Energy Act of 1946. The Act established the United States Atomic Energy Commission for the purpose of transferring nuclear weapons development and nuclear power management from military to civilian control. The Act established a US policy to prevent the spread of nuclear technology by secrecy and denial. Private development of nuclear energy did not start until the Act was amended under the Eisenhower administration's Atoms for Peace Program in 1954. The Program actively promoted peaceful applications of nuclear technology, establishing new scientific curricula and sending equipment to schools, hospitals and research institutions within the US and throughout the world. The first nuclear reactors in several countries were built under the Program. The enactment of the Atomic Energy Act of 1954 was a watershed moment in the civilian nuclear industry. It amended and refined the Atomic Energy Act of 1946 by enabling private companies access to technical information about production of nuclear energy and fissile materials and allowing for greater exchange of information with foreign nations as part of the Atoms for Peace Program. The 1954 Atomic Energy Act adopted the new goals of international cooperation and the development and utilization of atomic energy for peaceful purposes as a vehicle to support non-proliferation by averting further activities in the development of independent nuclear programs. Section 123 of the US Atomic Energy Act of 1954 authorized the conclusion of Agreements for Cooperation with other countries. An Agreement for Cooperation, commonly known as "123 agreement" established conditions for non-proliferation commitments and safeguards for nuclear technology supplied by the United States, including nuclear reactors, enrichment and reprocessing facilities and special nuclear material. The Atomic Energy Act of 1954, as originally drafted, did not prohibit

*This manuscript has been authored by an employee of Brookhaven Science Associates, LLC, under contract DE-SC0012704 with the US Department of Energy.

cooperating partner countries, through indigenous effort, develop nuclear weapons or other nuclear-related military applications. Strengthening of non-proliferation requirements and compliance progressed with the formation of the International Atomic Energy Agency (IAEA) in 1957 and the Treaty on the Non-Proliferation of Nuclear Weapons (NPT) that entered into force in 1970. The NPT represents a new international regime to control and verify that the sharing of nuclear technology does not contribute to nuclear proliferation either directly or indirectly. An online monograph (Rosenthal et al., 2019) provides a more comprehensive introduction to the safeguards systems and the history of the International Atomic Energy Agency. For more on various subjects related to IAEA safeguards see the “IAEA Safeguards Glossary” (IAEA, 2001).

Special nuclear material

A crucial step in the making of a fissile weapon is to acquire fissile material necessary to reach a critical mass (the minimum amount of fissile material needed to sustain a nuclear chain reaction). All currently deployed nuclear weapons are based on uranium enriched in the isotope U-235 or plutonium with high isotopic content of Pu-239. Both U-235 and Pu-239 are fissile nuclides in nuclear fuel for power reactors. Fresh (unirradiated) light water reactor (LWR) fuel typically has a U-235 enrichment of 3–5%. Neutron capture in U-238 (the dominant isotope in LWR fuel) breeds Pu-239. U-233 is a fissile isotope bred from thorium-232 by neutron capture in nuclear fuel based on thorium. While it may be possible to weaponize U-233 there is no public information on its actual implementation. For more information on fissile materials see Shusterman (2021).

The usefulness of nuclear material for use in a nuclear weapons program is commonly referred to as material attractiveness. From a safeguards perspective not all nuclear material is alike. Material attractiveness generally refers to key attributes of the material, such as isotopic content, chemical form, etc. Examples of categorization schemes for use in coarse comparison of material attractiveness include the US DOE material attractiveness categories I–IV for nuclear materials in DOE nuclear facilities (US DOE Order 474.2) (USDOE, 2015) and the IAEA safeguards categories described in the Safeguards Glossary (IAEA, 2001). Other schemes, such as the figures of merit (FOM), have been advanced to delineate the attractiveness or preferences for a range of nuclear materials in advanced nuclear fuel cycle (Bathke et al., 2012).

Technical difficulties and time required to build a nuclear weapon from using certain nuclear material are two general attributes for characterizing the material attractiveness. Relevant material properties for consideration are the type, quantity and quality of material. Two intrinsic features of nuclear material that are key in the IAEA safeguards categories are conversion time and significant quantity. Conversion time (IAEA, 2001) is the estimated time required to convert different forms of nuclear material to the metallic components of a nuclear explosive device. Significant quantity (IAEA, 2001) is the approximate amount of nuclear material for which the possibility of manufacturing a nuclear explosive device cannot be excluded and it includes unavoidable losses from conversion and manufacturing processes. As a general rule-of-thumb the attractiveness of nuclear material increases with shorter conversion time and smaller significant quantity. In terms of quality the IAEA distinguishes direct versus indirect use material. Direct use material is nuclear material that can be used for the manufacture of nuclear explosive devices without transmutation (the conversion of an isotope of one element into an isotope of another element through one or more nuclear reactions) or further enrichment. Indirect use material is all nuclear material which must be further processed (e.g. transmutation or enrichment) to produce direct use nuclear material. Table 1 based on Tables I and II in Section 3.13 of the IAEA safeguards glossary (IAEA, 2001) summarizes attributes of direct and indirect use nuclear materials.

Table 1 Direct and indirect use nuclear materials.

<i>Beginning material form</i>	<i>Conversion time</i>	<i>Significant quantity (SQ)</i>
<i>Direct use nuclear materials</i>		
Metal: Pu, HEU ($^{235}\text{U} \geq 20\%$), or ^{233}U	Order of days (7–10)	Pu ^a : 8 kg Pu
PuO ₂ , Pu(NO ₃) ₄ or other pure Pu compounds;	Order of weeks (1–3)	^{233}U : 8 kg ^{233}U
HEU or ^{233}U oxide or other pure U compounds		HEU ($^{235}\text{U} \geq 20\%$): 25 kg ^{235}U
MOX or other non-irradiated pure mixtures containing Pu, and U ($^{233}\text{U} + ^{235}\text{U} \geq 20\%$)	Order of weeks (1–3)	
Pu, HEU and/or ^{233}U in scrap or other miscellaneous impure compounds	Order of weeks (1–3)	
Pu, HEU or ^{233}U in irradiated fuel	Order of months (1–3)	
<i>Indirect use nuclear materials</i>		
<i>Beginning material form</i>	<i>Conversion time</i>	<i>Significant quantity (SQ)</i>
U ^b containing $< 20\%$ ^{235}U and ^{233}U	Order of months (3–12)	75 kg ^{235}U (or 10 t natural U or 20 t depleted U)
Th	Order of months (3–12)	20 t Th

^aFor Pu containing less than 80% ^{238}Pu .

^bIncluding low enriched, natural and depleted uranium.

The above table categories Pu and ^{233}U in metal form to have the highest attractiveness of nuclear materials, as they have the smallest SQ and shortest conversion time, followed by high enriched uranium (HEU, i.e. $^{235}\text{U} \geq 20\%$ by weight) metal that has a similar conversion time but a larger SQ. Direct use nuclear materials also include mixed oxide (MOX is a nuclear fuel that contains more than one oxide of fissile material, such as Pu recovered from used nuclear fuel mixed with depleted uranium) and non-irradiated pure mixtures containing Pu and $^{233}\text{U} + ^{235}\text{U}$ enriched to above 20%. Other parameters of nuclear materials that characterize their attractiveness or non-attractiveness for weaponization include critical mass, internal heat generation, dose rate and spontaneous fission (Bathke et al., 2012).

The nuclear fuel cycle

The nuclear fuel cycle of a reactor represents the progression of nuclear fuel from creation to disposal. It involves front-end steps to manufacture the fuel for use in nuclear reactors and back-end steps to manage and handle used or spent fuel. The following overview examines the non-proliferation aspects of the key elements of the nuclear fuel cycle. The discussion uses the uranium fuel cycle, Fig. 1, for illustration (see also Crawford (2021)).

At the front-end of the nuclear fuel cycle the enrichment stage is of primary proliferation concern. The bare critical mass of uranium metal has a direct correlation with its level of enrichment in ^{235}U (natural U contains about 0.7% ^{235}U), as depicted in Fig. 2 (Bari et al., 1996). The calculated critical mass for bare uranium spheres of various enrichments using the MCNP Monte Carlo code and its associated cross-section library show that there is a significant increase in critical mass for enrichments below 20%, a value consistent with the threshold for HEU. Appendix A in Bathke et al. (2012) presents the calculated bare critical mass for 40 actinide isotopes.

Nuclear weapons typically contain uranium enriched to 80% ^{235}U or more, which is known as weapons-grade uranium. It is a matter of more SWU (separative work unit, a quantitative measure of the work that need be invested in an enrichment process)

Fig. 1 Nuclear fuel cycle (USNRC graphics).

Fig. 2 Enrichment dependence of the critical mass of bare metallic uranium sphere.

to reach higher enrichment in an enrichment facility. The required SWU for a given throughput and final enrichment target is dependent on the enrichment of the feed and the tailings (depleted uranium by-product of enrichment). For a given SWU the energy requirement and the size of an enrichment facility are dependent on the sophistication of the enrichment technology. The time and energy required to enrich uranium is reduced generally by starting with a higher enrichment feed. In one estimate (NRC, 2009), the time for obtaining 1 kg of 90% ^{235}U would be reduced by a factor of about 4 if the facility had used 5% enriched uranium instead of the usual natural uranium as the feed. Also, the SWU requirements for producing HEU drop even further if the process leaves higher ^{235}U concentration than the usual 0.3% in the tailings.

A monograph (Krass et al., 1983) reviewed the impact of enrichment technology on proliferation. The clandestine network that transferred gas centrifuge technology from the Netherlands to Pakistan and on to Libya, Iran, and North Korea has brought enrichment to the forefront of proliferation. Potential for clandestine enrichment facilities and the breakout scenario, where a proliferating state acquires a nuclear weapon disregarding international safeguards and sanctions, present challenges to deter proliferation. Suggestions to enhance the safeguards of enrichment facilities include to only store enriched uranium offsite and in a chemical form not suitable for direct re-enrichment, such as uranium oxide (Wood et al., 2008). It is interesting to note that some of the requirements and actions mandated by the Joint Comprehensive Plan of Action (JCPOA), aka the Iran nuclear deal (IAEA, 2015) set limits on the enrichment capacity and cap the level of enrichment to 3.67% ^{235}U . The JCPOA is based on a framework agreement consisting of a short-term freeze of portions of Iran's nuclear program and an increased intensity of international inspections in exchange for decreased economic sanctions on Iran, as the countries work towards a long-term agreement. By curtailing Iran's nuclear capabilities and obstructing its path to a nuclear weapon in the near term, the JCPOA is designed to prevent Iran move away from the rule-based non-proliferation regime created by the NPT and including especially the IAEA safeguards systems. (Current status: In May 2018 the United States announced that it will no longer be a party to the JCPOA (US, 2018). We also note that the new administration which will be in place on January 20, 2021 has indicated the intention of returning to consideration of the JCPOA (NYT, 2020).)

Fuel fabrication plants for light water reactors (LWR) typically receive uranium from enrichment plants in the form of uranium hexafluoride (UF_6) and then a chemical process converts the UF_6 to uranium dioxide (UO_2) powder. A sintering process fuses the UO_2 powder to form fuel pellets. For mixed oxide fuel (MOX) the powder used to form fuel pellets consists of both UO_2 and plutonium dioxide (PuO_2). LEU and Pu are targets of proliferation at the fuel fabrication stage of the uranium fuel cycle. It is noted that the uranium enrichment level does not change at fuel fabrication plants.

Plutonium is one of the few elements that occur in nature only in trace quantities. In uranium fueled reactors Pu is a product of neutron capture and beta decay. A neutron absorption by ^{238}U forms ^{239}U which beta decays first into ^{239}Np then ^{239}Pu . The Pu

isotopic composition varies according to the level of fuel utilization or burnup. The buildup of ^{238}Pu and ^{240}Pu in reactor fuel over time (Shusterman, 2021) presents challenge to using power reactors to produce weapons-grade plutonium. Weapons-grade plutonium (USDOE, 1997) is typically about 93% ^{239}Pu and is obtained from low burnup uranium fuel. In the US plutonium containing between 80 and 93% ^{239}Pu is referred to as “fuel-grade” plutonium, while plutonium with less than 80% ^{239}Pu , typical of Pu isotopic in LWR and CANDU reactors at normal burnup, is referred to as “reactor-grade” plutonium. Decay heat in ^{238}Pu makes handling of the material in a weapon problematic. The high rate of spontaneous fission in ^{240}Pu can cause a nuclear weapon to pre-initiate, thereby jeopardizing its yield. Employing heavy water as the neutron moderator, such as CANDU reactor, affords much greater flexibility in the types of fuel that can be used, including natural uranium. CANDU reactors with natural uranium fuel and their operation as on-load or online refueling (Nichita, 2021) present special safeguards attention. IAEA has developed robust approaches for CANDU reactors to track core and spent fuel items. For example, special unattended bundle counters are used to monitor movement of irradiated fuel bundles from the reactor core to the spent fuel pond. It is noted that one of the stipulations in the JCPOA requires Iran to convert its heavy water research reactors from natural uranium to LEU to reduce weapons-grade plutonium output.

Extending the period between refueling enhances the proliferation resistance of the fuel cycle for several reasons. A longer cycle means higher burnup and less frequent fuel maneuver into and out of the reactor. A higher burnup increases the fraction of the even isotopes in the plutonium thereby reduces the attractiveness of the fuel for weapons utilization. Less fuel maneuver reduces the opportunity to introduce fertile material into the reactor for undeclared production of nuclear material. Unplanned shutdown in the pretext of retrieving leaky fuel is a diversion scenario to obtain low burnup fuel. Pin diversion is possible under a scenario of reconstituting leaky fuel rods instead of replacing the whole fuel assembly (for more on fuel design see Young (2021)). Reactor with a lifetime core is a concept that precludes the need of onsite refueling (IAEA, 2007). These reactors are being designed to rely on outsourced front-end and back-end fuel cycle services thus alleviates the operator to have enrichment or reprocessing capabilities. An example of a State forgoing the right to develop enrichment and reprocessing capabilities is the commitment made by the United Arab Emirates in the US-UAE Agreement for Cooperation (Blanchard and Kerr, 2010).

At the back-end of the nuclear fuel cycle the proliferation concern centers around access to plutonium either from the spent/used nuclear fuel or the process streams from fuel reprocessing facilities. The assessment in DOE/NN-0007 (USDOE, 1997) concludes even reactor-grade plutonium can be used to make nuclear weapons. Further, the assessment indicates the only plutonium isotopic that cannot realistically be used for nuclear weapons is nearly pure ^{238}Pu which generates so much heat that would render the weapon unstable.

The amount of ^{238}Pu in the plutonium isotopic vector of spent fuel is typically a few percent and depending on burnup can reach up to 8%. Denaturing the plutonium isotopic in nuclear fuel by increasing the ^{238}Pu content can reduce the attractiveness of the plutonium for use in nuclear weapons (Kessler, 2008; Sagara et al., 2005; Lloyd and Goddard, 2018). Using a set of figures of merit (FOM) for attractiveness, Bathke et al. (2012) estimated that only 8% ^{238}Pu is required to render the plutonium isotopic unattractive for an unadvanced proliferant state that requires reliably high-yield nuclear devices. An evaluation by Kessler (2008) confirmed that plutonium with up to 9% ^{238}Pu is weapons usable only if high technology is used. Non-nuclear weapon states (NNWS) are not expected to have access to high technology and if any nuclear yield is acceptable then the unattractiveness threshold for ^{238}Pu should be lowered accordingly (Kessler, 2008; Bathke et al., 2012).

The principal motivation to reprocess spent/used fuel from power reactors is to recycle fissile materials. The current standard method of reprocessing nuclear fuel is the PUREX (plutonium uranium redox extraction) process (IAEA, 2010; Long, 1978) (for more on this topic see Senentz (2021)), an aqueous method to recover uranium and plutonium from spent/used nuclear fuel for use in nuclear power reactors or nuclear weapons. The process extracts uranium and plutonium as separate product streams. Other reprocessing technologies have been under development to avoid separated plutonium. They include COEX, UREX and pyroprocessing, etc. COEX (Coextraction) (IAEA, 2010) a proprietary Areva process in which plutonium and uranium are extracted together, thereby making it more difficult to isolate plutonium than if PUREX were used. The two major products from the COEX process are pure uranium and a mixture of plutonium and uranium. The UREX+ suite of technologies (Laidler, 2008; Kumari et al., 2020) is developed by the US DOE for the reprocessing of LWR spent fuel and for meeting waste management goals by recycling actinides (a group of 15 metallic elements with atomic numbers from 89 (actinium) to 103 (lawrencium)) recovered from spent fuel in fast reactors. A common feature of the UREX+ aqueous processes is that there is no separation of pure plutonium in any stage of the reprocessing. The co-extraction of uranium with technetium (Tc) is the initial process stage for UREX+. Alternatively, U may be co-extracted with Pu and Np, as well as Tc. Further processing yields separated streams of U, Tc, Pu/Np, the transuranic elements (TRU) (mainly Np, Pu, Am and Cm), or a mixed U/Pu/Np stream. Pyroprocessing is also referred to as electrochemical processing (Laidler, 2008) (for more on this topic see Bourg (2021)). It is based on electrochemical separation performed in molten salts at elevated temperature. Separation of individual actinide elements depends on the relative free energy of formation of the actinide-chloride compounds. As a result, it is usually simple to collect a uranium product with low TRU contamination, while it is more difficult to separate any of the transuranic from one another. Consequently, pyroprocessing is designed to recover the TRUs together with uranium, the amount of uranium being set by processing operations. The stored product will be a U/TRU metallic ingot.

In 1998 the IAEA Director General provided a report to the IAEA Board of Governors (IAEA, 1998) with information that, if available in enough quantities in separated form, Np, and with considerably greater difficulty, Am could be used to manufacture nuclear explosive devices. The proliferation risk could certainly grow with fuel cycle choices that incorporate reprocessing technologies, such as the UREX+ suite, producing separated Am as one of the product streams. Short of putting Np and Am under

safeguards, the IAEA eventually developed and implemented a flow sheet verification technique at reprocessing plants subject to IAEA safeguards (Albright and Kramer, 2005; Rosenthal et al., 2019). Absent such monitoring, it is possible that States would be able to remove significant quantities of Am or Np from the plant clandestinely in order to manufacture nuclear weapons, either taking product streams of these materials or separating it from mixed product streams. Proliferation resistance studies have been performed on a comparative basis to evaluate reprocessing alternatives to PUREX (Bari et al., 2009). Using the figures of merit approach, Bathke et al. evaluated the material attractiveness of product streams from several reprocessing schemes for the LWR uranium fuel cycle, including UREX, COEX and PYROX (a pyroprocessing scheme) (Bathke et al., 2012). Their general conclusion is that co-extracting Pu with minor actinides (these are actinide elements in used nuclear fuel (spent fuel) other than uranium and plutonium, which are termed major actinides) does not reduce its attractiveness for use in nuclear weapons. However, extracting Am with Cm produces a product that is unattractive for use in a nuclear weapon. In the COEX process, where Pu is co-extracted with U, the U content determines the attractiveness level with higher proportions of U trending towards lower level of attractiveness.

Thorium fuel cycle

The first core of Indian Point Unit 1, a Babcock and Wilcox (B&W) Pressurized Water Reactor (PWR) in Buchanan, New York, used thorium-based fuel with stainless steel cladding. A thorium fuel cycle starts with the conversion of ^{232}Th to ^{233}U by neutron capture and beta decay (Shusterman, 2021). The only naturally occurring isotope of thorium is ^{232}Th . The absence of fissile isotope in thorium requires the thorium fuel cycle to rely on fissile fuel, like ^{235}U or ^{239}Pu , to establish and sustain a fission chain reaction that can provide excess neutrons to start the ^{233}U production. ^{232}Th , the fertile component in the thorium fuel cycle, is thus analogous to ^{238}U in the U–Pu fuel cycle. There is no plutonium in a thorium fuel cycle. However, ^{233}U is under IAEA safeguards because in many respects it is well suited for nuclear weapons use, such as a low critical mass, low spontaneous fission neutron source and low heat output. The proliferation concern for a thorium fuel cycle are the diversion of ^{233}U and the misuse of reactor to produce ^{233}U clandestinely (Kang and von Hippel, 2001; Uribe, 2018). The ^{232}U co-produced with ^{233}U in a thorium fuel has ^{208}Tl daughter products that emit highly energetic (2.6 MeV) gamma rays with high absolute emission probability. Gamma radiation from ^{208}Tl presents challenges not only to operation and monitoring but also to the potential proliferator. Some people argue the radiation exposure may not be a sufficient deterrent to a technically advanced proliferator. In some proliferation scenarios, ^{233}Pa a precursor to ^{233}U , may be removed from a reactor, such as from a molten salt reactor (MSR), allowing formation of ^{233}U without the undesirable ^{232}U (Uribe, 2018). Considering the spectrum of MSR designs and material flowsheets (for more on MSR see Ignatiev (2021)) several safeguards challenges were noted (Kovacic et al., 2018) including nuclear material measurement methods and technologies need to be developed (destructive/non-destructive analysis, etc.) given that the nuclear signatures are likely to be notably different from conventional LWR fuel cycles.

Research reactors

Research reactors primarily serve as a neutron source for research and isotope production. Early designs often use HEU for fuel to increase the power density in a more compact configuration and reduce the frequency of refueling. There has been a movement to convert existing research reactors from HEU to LEU (Glaser, 2002). A mission to develop new fuel for research reactors to increase their proliferation resistance was initiated by the IAEA International Nuclear Fuel Cycle Evaluation (INFCE) conference (IAEA, 1980) in the late 1970s. In 1978 the US Department of Energy initiated the Reduced Enrichment for Research and Test Reactors (RERTR) Program (<https://www.rertr.anl.gov/>) to develop the technical capabilities and resources to convert research reactors and isotope production processes from using HEU to LEU through the development of new LEU fuels and targets. For more on research reactors see O’Kelly (2021).

A global fuel cycle

A variety of programs have looked at developing an international fuel cycle or a reliable supply of fresh fuel and spent fuel take-back arrangements to encourage aspiring nuclear energy states to forgo the development of an indigenous sensitive nuclear infrastructure, thereby minimizing the proliferation potential for these aspiring states. Mohamed ElBaradei, former director general of the IAEA, had called for the establishment of a multinational nuclear fuel bank, envisioning that such a fuel bank would remove the incentive for countries to develop their own enrichment and reprocessing facilities, and consequently would minimize the proliferation risk posed by countries seeking nuclear energy (IAEA, 2005). In such a system, however, incentives for participation must be coherent and compelling and must alleviate the anxieties of states vying for energy independence by providing an economic and assured fuel supply. Programs must address the issues of where multinational facilities will be located and who will provide the fuel, without making states feel that they are being held hostage or abdicating their right to peaceful nuclear technologies as granted by Article IV of the NPT. Many issues related to the multinational approaches to the nuclear fuel cycle were examined in a series of articles published by the American Academy of Arts and Sciences (AAAS, 2009, 2010a,b). A joint committee of the US National Academy of Sciences (NAS) and the Russian Academy of Sciences (RAS) produced a report (NRC, 2009) analyzing the proposals and options

for future international nuclear fuel cycles, including the incentives that might be required for countries to accept fuel assurance guarantees and not develop enrichment or reprocessing facilities, as well as technical fuel-cycle issues. One of the joint committee's recommendations is that developers of nuclear fuel cycle technologies should assess the technologies' proliferation risks and projected economic costs and benefits as critical elements of design. For more information on global fuel cycle see also [McKinzie \(2021\)](#) and [Hore-Lacy \(2021\)](#).

Evaluating proliferation risk

In order to reduce proliferation risk of deploying nuclear energy more globally, risk assessments of the threats and consequences of a potential proliferation event are necessary. Methods addressing the technical aspects of proliferation resistance have been developed, most notably the Proliferation Resistance and Physical Protection methodology ([GIF, 2011b](#)) of the GEN IV International Forum (GIF). Such methodologies, however, have concentrated on the technological factors of proliferation resistance, but have not addressed the equally important political factors. Many of the nonproliferation efforts in the geo-political arena are discussed in a Special Section on Nonproliferation in The November 2010 issue of the Nuclear News, a publication of the American Nuclear Society. It is recognized that there are large uncertainties in evaluating the impact of national nuclear policy on non-proliferation. After conducting a review of worldwide research activities on nuclear non-proliferation a proliferation evaluation framework was proposed ([Wu et al., 2020](#)). The new assessment framework utilizes the analytic hierarchy process (AHP) to quantify the weight of national policy, among other extrinsic and intrinsic barriers, in influencing the outcome of nuclear non-proliferation. AHP had been applied previously in a comparative study of nuclear fuel cycles and the three cycle options (once-through, thermal recycling using MOX fuel and fast reactor recycling employing pyro-processing) were ranked against five attributes: sustainability, environmental friendliness, economics, proliferation resistance and technical feasibility ([Yoon et al., 2016](#)).

Several steps are involved in preparing a good evaluation of the proliferation risk or resistance of a nuclear energy system or facility. First, one must determine how to characterize and measure proliferation resistance or risk, and, second, one must evaluate the risk or resistance. Most research on proliferation resistance and risk has focused on these steps. Nuclear proliferators may be states, state-sponsored terrorists, or in dependent non-state actors. Each of these proliferators possesses differing motives, tactics, and means that dictate how the system should be optimally safeguarded and protected. In addition, there are intrinsic features of the system that could delay or present technical difficulties to the proliferator.

The Generation IV Roadmap ([GIF, 2002](#)) defined the following Proliferation Resistance and Physical Protection (PR&PP) goal for future nuclear energy systems:

Generation IV nuclear energy systems will increase the assurance that they are a very unattractive and the least desirable route for diversion or theft of weapons-usable materials, and provide increased physical protection against acts of terrorism.

The Proliferation Resistance and Physical Protection Working Group (PRPPWG) was created to develop, implement and foster use of an evaluation methodology ([GIF, 2011b](#)) to assess Generation IV nuclear energy systems ([Stanculescu, 2021](#)) with respect to the GIF PR&PP goal. The following is a brief discussion of the PR&PP methodology for evaluating proliferation resistance.

The overall PR&PP framework involves three steps: challenges, system responses, and outcomes, shown in [Fig. 3](#). For a proliferation risk scenario occurring at a nuclear facility, "challenges" are threats to the nuclear facility, such as diversion, misuse, breakout, or the establishment of a clandestine facility. System responses to the challenge are then evaluated, for example, whether there are physical and technical design features that would combat or slow this particular attempt or safeguards in place that would alert the international community. Finally, the possible outcomes resulting from the challenge and the system response are evaluated. These steps are repeated for many potential challenges and system response variations.

Fig. 3 The PR&PP methodology framework.

The PR&PP analysis of the system response occurs in three stages. First, the nuclear system is decomposed into system elements to permit a pathway analysis. This involves identifying elements such as the materials, facilities, processes, and transportation links that an adversary could exploit to accomplish his or her goals. Second, the location of operations and materials, their accessibility, and characteristics are identified. In addition, any extrinsic measures and the locations where they are applied are noted, such as material balance areas and locations of safeguards and physical protection systems. Finally, interfaces with other systems that are not part of the analysis (i.e., links to clandestine facilities) are evaluated to identify any additional potential vulnerabilities.

In assessing the degree of proliferation resistance of a nuclear system both intrinsic and extrinsic features/barriers are considered. Intrinsic features relate to physical design features of a nuclear energy system; hence, intrinsic barrier: physical design features that impede proliferation, sabotage or theft. Extrinsic or institutional features relate to States' commitments, obligations, and policies regarding nuclear non-proliferation. Hence, extrinsic barriers include treaties, agreements, the application of IAEA safeguards, and security forces and equipment to impede proliferation, sabotage and theft. Examples of intrinsic and extrinsic features are presented in [IAEA \(2002\)](#), [USDOE \(2000\)](#), [USDOE \(2001\)](#) and [IAEA \(2008\)](#).

Intrinsic features consist of technical features that:

- (a) Reduce material attractiveness for use in nuclear weapons programs;
- (b) Prevent or inhibit diversion of nuclear material;
- (c) Prevent or inhibit undeclared production of direct-use material, including reactors designed to prevent undeclared target materials from being irradiated in or near the core; reactor cores with small reactivity margins to prevent operation of the reactor with undeclared targets; and fuel cycle facilities and processes that are difficult to modify
- (d) Facilitate nuclear material accounting and verification, including continuity of knowledge.

Extrinsic features consist of:

- (a) Commitments, obligations and policies of States, such as the Treaty on the Non-Proliferation of Nuclear Weapons and the IAEA safeguards agreements and protocols additional to such agreements;
- (b) Agreements between exporting and importing states on exclusive use of nuclear energy systems for agreed purposes;
- (c) Commercial, legal or institutional arrangements that control access to nuclear material and technology;
- (d) Verification measures by the IAEA or by regional, bilateral and national measures; and
- (e) Legal and institutional measures to address violations of measures defined above.

For comparing the relative risk of different proliferation scenarios, separate measures for proliferation resistance (PR), which is relevant to the Host State threat, and physical protection (PP) robustness, which is relevant to non-state threats, have been developed under the PR&PP approach. For proliferation resistance (PR) the measures are:

- *Proliferation Technical Difficulty (TD)*—The inherent difficulty, arising from the need for technical sophistication and materials handling capabilities, required to overcome the barriers to proliferation.
- *Proliferation Cost (PC)*—The economic and staffing investment required to overcome the technical barriers to proliferation including the use of existing or new facilities.
- *Proliferation Time (PT)*—The minimum time required to overcome the barriers to proliferation (i.e., the total time planned by the Host State for the project).
- *Fissile Material Type (MT)*—A categorization of material based on the degree to which its characteristics affect its utility for use in nuclear explosives (e.g., bare sphere critical mass, neutron emissions, decay heat).
- *Detection Probability (DP)*—The cumulative probability of detecting a proliferation segment or pathway.
- *Detection Resource Efficiency (DE)*—The efficiency in the use of staffing, equipment, and funding to apply international safeguards to the nuclear energy system.

For physical protection (PP), the measures are:

- *Probability of Adversary Success (Ps)*—The probability that an adversary will successfully complete the actions described by a pathway and generate a consequence.
- *Consequences (C)*—The effects resulting from the successful completion of the adversary's action described by a pathway.
- *Physical Protection Resources (PPR)*—the staffing, capabilities, and costs required to provide PP, such as background screening, detection, interruption, and neutralization, and the sensitivity of these resources to changes in the threat sophistication and capability.

Example applications of the PR&PP methodology include a case study of an example sodium fast reactor ([GIF, 2009](#)) and a compendium report that examined the PR&PP characteristics of each of the six GIF nuclear energy systems ([GIF, 2011a](#)). The report ([GIF, 2011a](#)) captures the current salient features of the GIF system design concepts that impact their PR&PP performance. Appendix A to the report provides an extended table which lists, in summary form, each design concept and its robustness characteristics in response to potential PR&PP threats to the design.

An early application of the GIF PR&PP methodology was its adaptation in the assessment framework ([Bari, 2008](#)) for the draft nonproliferation impact assessment (NPIA) ([NNSA, 2008](#)) of the Global Nuclear Energy Partnership (GNEP). GNEP was part of President Bush's Advanced Energy Initiative (announced in 2006 and domestic components terminated in 2009), aiming to expand nuclear energy while reducing nuclear waste impacts and risks of nuclear proliferation. The draft NPIA evaluated GNEP programmatic alternatives by using technical factors and policy factors. The assessment framework ([Bari, 2008](#)) developed the linkage between the technical factors and the PR&PP methodology, aligning the technical factors with associated PR&PP measures and their

underlying metrics. **Table 2** is a crosswalk between the three technical factors and the associated PR&PP measures. The metric for each PR&PP measure provided the foundation of a grading structure for the technical factors, giving qualitative notion of time and scale of possible consequence.

The draft NPIA (NNSA, 2008) conducted comparative assessments of the nonproliferation features of the GNEP alternatives. The study considered three fuel cycle alternatives, once-through, full actinide recycle and partial actinide recycle, and included both fast and thermal reactors. For thermal reactors, in addition to the LWR, the other alternatives were heavy water moderated reactor (HWR) and high temperature gas-cooled reactor (HTGR). The draft NPIA compared the nonproliferation impacts of alternatives by assessing several PR&PP attributes of each alternative, including demand for enrichment services (e.g. HTGR was higher than HWR), risk of misuse (e.g. HWR was higher than LWR), risk of separating weapons-usable material (e.g. recycle was higher than once-through), material attractiveness (e.g. recycled fuel was higher than once-through fuel) and safeguards cost (e.g. HWR was higher than LWR).

Concurrently, a multi-laboratory team (Zentner et al., 2010), using the GIF PR&PP methodology, evaluated the proliferation resistance technical risk characteristics of a number of generic nuclear reactors types in a variety of fuel cycle implementations. They included a sodium fast reactor, a high temperature gas reactor, a heavy water reactor, and a light water reactor. Three general types of material acquisition scenarios were evaluated for each reactor type: (1) concealed diversion of material; (2) concealed misuse of the reactor to produce materials; and (3) breakout. The evaluations considered both the intrinsic and extrinsic PR&PP characteristics of each reactor. This study showed that each reactor type has particular features affecting its respective PR&PP characteristics and that no type was clearly superior or inferior for the material acquisition scenarios considered. Areas were identified where safeguards approaches and technology could be improved to enhance the safeguardability of the designs. For example, minimizing the number of entry and exit points for fuel transfer between system elements will enhance material containment, protection, and accountability (MCP&A), thus partially compensating for any lack of knowledge continuity by visual inspection during a fuel transfer. Another design feature with potential to reduce the risk of misuse is the modern approach of using burnable poisons in LWR fuel assemblies. Its implementation results in fewer guide tubes in PWR fuel assemblies, complicating misuse by insertion of target rods in the guide tubes. Many advanced reactor designs under research and development incorporate intrinsic proliferation resistance features, in particular in the fuel cycle architecture. Some micro (typically up to 10 MWe) reactor designs that feature lifetime cores (IAEA, 2020) can operate up to 20–30 years without refueling. These so-called ‘nuclear batteries’ replace their cores as a whole in a dedicated fuel facility, simplifying the fuel cycle infrastructure and its related safeguards requirements. Some fast reactor designs practice breed-and-burn that sustains fission power generation with minimal need for enrichment. The Traveling Wave Reactor-Prototype (TWR-P) (Hejzlar, 2021), for example, only needs enriched uranium for its first fuel loading (to establish criticality), and thereafter it is fed only with natural or depleted uranium and operated on the once-through fuel cycle for very long core life (~60 years) with no need for reprocessing and enrichment. There is also a scenario of deploying floating nuclear power plants (Golay and Kodak, 2021) whereby the supplier provides all fuel services from cradle-to-grave such that the host nations do not need to have their own infrastructure for enrichment, fuel fabrication and spent fuel storage and disposal, thus minimizes the risk of proliferation.

Prospects of mitigating proliferation risk

For nuclear energy, proliferation resistance does not mean proliferation proof; there is no panacea for the ever-dynamic evolution of the nature of proliferation threats. Ultimately, no fuel cycle, technology, or international policy can entirely eliminate the possibility of nefarious proliferation of nuclear expertise, technology or materials. The risk of nuclear proliferation, however, can be mitigated with a balanced approach that includes intrinsic proliferation resistance inherent to technology design and material management, in conjunction with extrinsic efforts through safeguards, international collaboration, and verifiable treaties. The incorporation of each of these approaches, both technical and institutional, should work in tandem to produce a risk-informed proliferation-resistance strategy.

Proliferation resistance can raise hurdles, slow progress, and provide alarm signals of proliferation activity. Risk assessments of the threats and consequences of a potential proliferation event are thus necessary to reduce proliferation risk. There are many

Table 2 Correspondence between NPIA technical factors and PR&PP measures.

<i>Technical factors</i>	<i>Associated PR&PP measures</i>
Avoiding proliferator success (T1)	• Technical Difficulty (PR) • Proliferation Cost (PR) • Proliferation Time (PR) • Detection Probability (PR) • Probability of Adversary Success (PP) • Consequences (PP)
Facilitating cost effective international monitoring (T2)	• Safeguards Cost (PR) • Detection Probability (PR) • Security Cost (PP)
Resulting in less attractive material types and forms (T3)	• Material Type (PR) • Consequences (PP)

potential pathways to proliferation, and adversary success is highly dependent on pathway choice and creativity. In addition, the results and applicability of an analysis are dependent on a number of assumptions about adversary capabilities and objectives. These uncertainties make it difficult to effectively collapse the proliferation resistance of a facility into a single value denoting overall proliferation resistance. However, one key conclusion has emerged from the work performed to date for PR&PP: Safeguardability is a very important consideration. The PR&PP methodology provides designers and policy makers a generic and formal comprehensive approach to evaluate, through measures and metrics, the Proliferation Resistance (PR) and Physical Protection (PP) characteristics of advanced nuclear systems. As such, the application of the evaluation methodology offers opportunities to improve the PR and PP robustness of system concepts throughout their development cycle.

Safeguards-by-design (SBD) is generally recognized as an approach wherein international safeguards are fully integrated into the design process of a nuclear facility—from initial planning through design, construction, operation, and decommissioning. In a workshop (IAEA, 2009), safeguards and facility design experts convened to discuss basic principles to design and implement an SBD process and to identify fundamental design features deemed critical to the effective and efficient implementation of IAEA safeguards. The PR&PP evaluation could be an integral part of the SBD process, to elucidate the interactions between the intrinsic and the extrinsic features, study their interplay, and then guide the path towards an optimized design. The SBD process was applied to an advanced CANDU reactor design (ACR-1000) (Whitlock, 2010) using the PR&PP methodology. The pathway comparison consisted of a simplified qualitative ranking based on expert elicitation. Results of this exercise were used to stimulate discussions involving the design team, the state regulator, and the IAEA, and propose steps that accommodate safeguards without negatively impacting other design requirements. The GIF PR&PP Working Group is implementing an SBD process to evaluate the GEN IV system designs (Cojazzi et al., 2018; Cheng et al., 2019).

There are now many new and diverse developments and applications of peaceful nuclear energy in many countries. It is of paramount importance that the development of new designs of reactors and fuel cycles incorporate enhanced intrinsic proliferation resistance especially during the early stages of design. It is the aspiration of Generation IV nuclear energy systems to increase the assurance that they are a very unattractive and the least desirable route for diversion or theft of weapons-usable materials, and provide increased physical protection against acts of terrorism. Adherence to stringent and powerful international safeguards regime throughout the entire lifecycle of nuclear energy systems also provides confidence that proliferation risk can be mitigated and reduced to a level acceptable by society.

The fuel cycle

The nuclear fuel cycle considered in this chapter assumes nuclear power reactors cooled and moderated by regular water (Light Water Reactors or LWR). The international fuel cycle center concept applies to all types of nuclear reactors, including advanced future generation reactors ([Krepel, 2021](#)), ([Stanculescu, 2021](#)).

The fuel cycle starts with natural uranium that is mined which needs to be processed in the milling step ([Crawford, 2021](#)) and converted to uranium hexafluoride which then needs to be enriched in Uranium 235 from 0.7% to between 3% and 5% ([World Nuclear Association, 2020b](#)). Once enriched, the U235/U238 powder is converted into pellets and they are inserted into fuel pins and arranged into fuel assemblies to be loaded into the nuclear reactor for 3–4 years of operation. These fuel assemblies constitute the “core” of the reactor. Once removed from the reactor, the used fuel can either be directly disposed after about 5 years of on-site storage in spent fuel pools of water, stored on an interim basis in dry cask storage casks or reprocessed and then recycled. The residual waste, either as used fuel or reprocessed high level waste (HLW), needs to be disposed in a geological repository. [Fig. 1](#) highlights the key steps in the fuel cycle.

The problem

The problem with this fuel cycle is that at various points it is susceptible to diversion of special nuclear materials (primarily Uranium 235 and Plutonium 239) for the purpose of making nuclear weapons. The major points of vulnerability are during the enrichment and reprocessing step. While enrichment of uranium is required to produce nuclear energy, reprocessing is not. Reprocessing is an added step to recycle unused uranium 235 and plutonium 239 which is produced during operation ([World Nuclear Association, 2020a](#)). This recycling has two objectives: (1) to reduce demand for mining of uranium to extend the supply of uranium; and (2) to reduce the volume of high level nuclear waste that needs to be geologically disposed by 90% compared to direct used fuel disposal. It is interesting and important to note that there has not been a case where reactor grade plutonium (without complicated reprocessing technology) has been used to make a nuclear weapon. The feasibility of using “reactor grade” plutonium for weapons is in doubt but it is assumed to be a proliferation risk should use fuel be stolen.

Another nuclear technology that requires reprocessing are “breeder” or “burner” reactors. One type of this class of reactors is called “fast”¹ reactors which use liquid sodium as a coolant instead of water to allow for “breeding” Plutonium 239 from natural uranium (mostly U-238). These reactors will avoid the environmental impact of uranium mining and the enrichment since Pu-239 is fissionable and can power the nuclear reactor. Breeder reactors can make at least as much Pu-239 (by neutron capture in U-238) as they consume. There is enough U-238 in storage left over from uranium enrichment plants to power such breeding nuclear energy plants for thousands of years making nuclear energy “sustainable.” This technology is unique in that it takes a non-fissionable “waste” from enrichment (U-238) and converts it in the reactor to make Plutonium 239 as a result of the neutronic reaction during operation ([Boullis, 2021](#)). Depending on the design of the core, more plutonium can be produced than is consumed during operation which is why it is called a “breeder.”

The so called “burner” reactors can use the same fast reactor sodium cooled core but are designed to only consume the Plutonium generated in contemporary light water reactors and not breed it. The first operating reactor in the United States to produce electricity was a sodium cooled fast reactor built in Idaho at the Idaho National Laboratory. Breeder reactors are operating in Russia and once operated in France and the United States. The United States breeder reactor program was politically shutdown due to concerns about proliferation.

¹The term fast is used since the reactor uses higher speed neutrons instead of slow thermal energy neutrons needed for Light Water Reactors.

Fig. 1 Nuclear fuel cycle. <https://www.sciencedirect.com/topics/materials-science/nuclear-fuel-cycle>

Most nations with developed nuclear energy programs have the capability of natural uranium enrichment which is a requirement for self-sufficiency in nuclear energy production. Most nuclear nations also have reprocessing² capabilities including China, Russia, France, United Kingdom and the United States (for military uses) (World Nuclear Association, 2020b). The US has decided not to reprocess commercial used fuel to set an example to other nations to forego this technology with little success.

With many new emerging nations seeking to use nuclear energy for power production, concerns exist for proliferation of the special nuclear materials. For this reason, international fuel cycle centers have been proposed to avoid the need for each nation that seeks to use nuclear energy to develop their own proliferation risk technologies. Those nations that have reprocessing capability have high security proliferation resistant systems in place with checks by the International Atomic Energy Agency to monitor the location of these special nuclear materials.

The solution

The concept of an international fuel cycle center would be to have a nation, likely a nation that already has the infrastructure and facilities to perform not only enrichment, and fuel fabrication, but also reprocessing and recycling at the same secure facility, host such a facility under IAEA supervision (Richter, 2008). While combining all these functions at one facility is not necessary, it would limit the security requirements associated with separate facilities. The challenge is to get agreement from the other nations to assure them that they can have a reliable supply of fuel for operations. The hope is to avoid the national desire to “become a nuclear weapons nation” for the status that it provides. We have such examples in North Korea, Indian, Pakistan, and Iran.

The backbone of the effort to limit the spread of nuclear weapons and technology is the Non-Proliferation Treaty of International Atomic Energy Agency (1970). The goal was to limit the spread of nuclear weapons while affording nations the opportunity for development of peaceful applications of nuclear science and technology including energy production. The International Atomic Energy Agency is charged with overseeing compliance by hosting inspections of nations with nuclear programs. At this point 191 nations have signed the treaty.

²Reprocessing is currently used to recycle unused uranium from used fuel and recycled in LWRs. Plutonium is also recycled in LWRs by mixing with uranium creating Mixed Oxide (MOX) fuel which is being done in France. This can save about 25–30% of uranium resources by extracting this unused energy in uranium.

While this effort has been largely successful, India, Pakistan and Israel have not signed the Treaty and have nuclear weapons. North Korea signed and then resigned from the Treaty which has led to their development of an atomic bomb. Although Israel has not declared itself as a nuclear weapons state, it is widely believed it have them. As a counter, Iran is suspected of developing nuclear weapons despite assurances not to do so. Iran has its own independent enrichment plant capable of enriching uranium to levels needed for nuclear weapons with only one operating nuclear power plant.

In an effort to deal with these evolving threats and nations that desire to have access to nuclear technology, the then Director General of the Atomic Energy Agency in 2003, Dr. Mohamed ElBaradei, published a paper entitled, "Towards a Safer World" (ElBaradei, 1970). In this article, he recommended, among many other things dealing with weapons proliferation, to limit reprocessing and enrichment to facilities under multinational control with assurances to user nations that there would be a reliable, non-political source of supply. The obvious difficulty of his proposal was dealing with national security and economic interests of the nations. His proposal was complicated by the globalization of countries' own existing fuel production facilities in terms of placing them under international control. The barriers to obtaining agreement on surrendering their rights to enrich and reprocess dwell on trust of the multilateral agency to be non-discriminatory and transparent in its dealings.

As a result of the ElBaradei initiative, many proposals were considered including the creation of IAEA's international emergency fuel supply to deal with possible disruptions for enrichment (Carrell-Billiard and Wing, 2010). In 2007, ElBaradei presented a report to the IAEA Board of Governors (all member states) entitled "Possible New Framework for the Utilization of Nuclear Energy" (ElBaradei, 2008). In this report he calls for the creation of an international fuel bank to avoid the need for country's to build enrichment plants funded by member states and individual contributions. As a result several nations, the United States, Germany, Austria, Russia and the World Nuclear Association presented proposals to forward the concept of international fuel cycle facilities (World Nuclear Association, 2011), (Simpson, 2009), (National Research Council, 2009).

The challenges

The challenge is that there are only four places to enrich natural uranium—the United States (URENCO-USA foreign owned and operated), Eurodif (which is internationally owned but operated by the French), URENCO (internationally owned and operated) and Russia (state owned and operated). China has been enrichment and reprocessing capabilities but so far has them for their domestic market. The concern is that since the number of options are few, assurance of supply and putting the nation's electricity supply at the political mercy of these countries is not necessarily viewed as a sound policy. What ElBaradei and others sought to achieve is to provide an IAEA independently managed stockpile of enriched uranium to those countries who forgo enrichment. With this stockpile, nations would then be able to purchase fuel fabrication services from at least 16 countries worldwide eliminating concerns about diversity of supply.

The most ambitious new proposal was the Global Nuclear Energy Partnership (GNEP) proposed by President G.W. Bush of the United States in Department of Energy (2007). GNEP called for a consortium of nations with advanced nuclear programs to enter into supply arrangements for nuclear fuel and to take back the used fuel from nations who agree to forgo enrichment and reprocessing. GNEP also called for development of reprocessing technologies that would be less proliferation prone. The big incentive for the GNEP program was the return of the used fuel which makes dealing with their nuclear waste less of a problem. Ultimately, the high level nuclear waste from reprocessing might be have to be returned to the host country for storage or disposal. There are companion proposals to host international disposal centers (Hore-Lacy, 2021) to avoid the need for each nation building its own geological repository for their nuclear power program.

Due to the difficulties in obtaining agreement with participant nations to forego enrichment and reprocessing as a pre-condition, the United States modified the proposal to sign separate memoranda of understandings for a guarantee of supply. Despite these heroic efforts in 2009, the United States changed administrations to democrats who bizarrely defunded the entire effort due to the concerns about reprocessing as "undermining the Nation's non-proliferation policy."

International Uranium Enrichment Centers

Because of the difficulties in obtaining a more complete agreement on the nuclear fuel cycle, ElBaradei focused on the more immediate and important question of enrichment which is the easiest path to nuclear weapons while also an important first step in using nuclear power. Establishing an enrichment program is costly and complicated which is why nations might support an international enrichment supply system. Reprocessing is even more complicated and costly and likely unneeded at their early stage of a nuclear energy program. The high cost of developing either or both of these capabilities is a big disincentive for new nuclear nations.

One successful program that did move forward was the Russian establishment of a low enrichment uranium reserve with agreement with the IAEA. Russia established an "International Uranium Enrichment Center" (IUEC) in Angarsk, Siberia in 2007 with Kazakhstan, Ukraine and Armenia as initial shareholders and members (IAEA, 2007). In 2010, this facility won acceptance by the IAEA as an emergency storehouse of low enriched uranium (4.95%) under IAEA control (International Uranium Enrichment Center, 2010). For nations seeking to withdraw LEU from the emergency supply it must meet "established non-proliferation criteria."

The IUEC has already placed 120 t of low enriched uranium in storage for use of all IAEA member countries as an emergency reserve due to political constraints from purchasing on the commercial market. This facility is under IAEA safeguards as a monitored facility. The other interesting feature of the IUEC is that the technology is "black boxed" which means the owners will not have

Fig. 2 International uranium enrichment center fuel bank. http://eng.iuec.ru/activities/fuel_bank/

Table 1 Fuel bank operating criteria.

Amount of reserve	More than 120 tU LEU as uranium hexafluoride (UF ₆)
Enrichment	From 2.00% up to 4.95%; not less than one third of the reserve (40 tU) with an enrichment of 4.95%
Location	JSC IUEC storage sites within the Angarsk Electrolysis Chemical Complex
Financing	The guaranteed reserve is created and maintained at the expense of the Russian Federation
Selling price	Based on spot market prices published by internationally acknowledged companies
JSC IUEC functions	Storage, maintenance and sales of LEU from the guaranteed reserve

access to the technology, only the service of enrichment and materials. This is the first such agreement on fuel cycle technology that could serve as model for others including reprocessing services. Fig. 2 shows how functionally this system works (International Uranium Enrichment Center, 2020). The Russian concept appears to meet ElBaradei's goals for at least one step to a "safer world."

The basic parameters under which this center operates are shown on Table 1.

Concluding remarks

No nuclear fuel cycle can be made completely risk free. Although reprocessing and enrichment technologies can be made more proliferation resistant and secure, reducing proliferation risk is a political not technical decision (Chang and Bari, 2021). It is clear however, that as more countries seek to obtain the benefits of nuclear energy increasing the number of enrichment and reprocessing facilities, the larger the risk even under the most secure conditions. An individual country can chose to "break out" and build a nuclear weapon with these technologies unless politically and economically incentivized not to do so. It is important to establish international fuel cycle centers to discourage individual countries from developing their own enrichment and reprocessing capabilities. However, guarantees and incentives are needed to enable such agreements among nations so that may be assured of nuclear fuel for their operating nuclear power stations.

The current commercial nuclear fuel cycle market can handle the current demands for uranium fuel and reprocessing needs. The IAEA fuel cycle bank addresses a major step forward avoiding the need for nations to build their own enrichment plants if there is trust in the system and the commercial market accommodates the need. The reprocessing facility in France already serves the international market with the production of Mixed Oxide Fuel from recycled Plutonium being used in Japan, France and other countries. The so called "closing" the fuel cycle with the use of breeder or burner reactors and a centralized nuclear waste repository awaits leadership similar to that shown by the Russian government in their creation of the International Uranium Enrichment Center.

What is a “nuclear waste”?

Nuclear waste (NW) in its broadest sense are radioactive materials produced by nuclear industry (including nuclear research facilities) or nuclear defense activities for which no further use is foreseen in a given country in accordance with its national legislative and regulatory framework. NW may arise in a wide range of concentrations of radionuclides and in a variety of physical and chemical forms. These differences result in an equally wide variety of options for their management and processing the more so that practices and terminologies as well as regulations differ from different countries. Classifying NW is therefore needed in order to implement and optimize appropriate management systems adapted to their physical/chemical characteristics.

To this regard, the IAEA (International Atomic Energy Agency) has published a reference document ([IAEA SAFETY STANDARDS, 2009](#)) which sets out a general scheme for classifying radioactive waste (that include NW) which is based primarily on considerations of long-term safety, and thus, by implication, disposal of the waste. This “Safety Guide” identifies the conceptual boundaries between different classes of waste and provides guidance on their definition on the basis of long-term safety considerations. This classification is mainly based on two parameters that characterize a radioactive waste: its “activity content” (a generic term that covers activity concentration, specific activity and total activity) and half-life of the radionuclides contained in the waste (time after which its radioactivity has been halved).

As a practical matter, nearly all the nuclear waste of concern to the public is made of radioactive products contained in the spent fuel which is unloaded from nuclear reactors when it has been fully used in the reactor core to produce its energy (hence the term “used fuel” or “spent fuel”). These radioactive products consist of two main categories. The first one comprises all fission products (FPs) which are directly created from fissions of atomic nuclei that are broken by neutrons into two pieces in the reactor core ([Klay, 2021](#)). The second is made up of actinides (or transuranics), which originate from various nuclear reactions (mainly neutron captures) on heavy nuclei (mainly uranium) during irradiation in the reactor core. The primary actinide is plutonium (Pu) and the other more common ones referred to as “minor actinides” (MAs) are neptunium (Np), americium (Am), and curium (Cm).

What to do with spent nuclear fuels (SNFs)?

When SNFs are unloaded from the reactor they are temporarily stored at the reactor site in 40-ft-deep water pools ([Glatz, 2021](#)). Then, the main question that arises is what to do with these highly radioactive SNFs? There are two options. The first one is to dispose of SNFs permanently (that is without further use) in an appropriate deep geological media once having encased them in leak proof shielded casks. Until final disposal, spent fuel can be stored in above ground shielded casks at interim storage facilities either at the reactor site or in a centralized storage facility ([Kessler, 2021](#)). This option is called “open” (or “once-through”) fuel cycle.

The second option is to “reprocess” SNFs in order to separate its constituents and then specifically manage each of them. In effect, it is a unique characteristic of nuclear energy is that used fuel may be reprocessed to recover fissile and fertile materials in order to recycle them in nuclear reactors. For a light water reactors either Pressurized or Boiling the main constituents in the used fuel are: uranium (which still contains about 0.8–0.9% of U235 fissile isotope and which makes up about 94% of the used fuel; plutonium

(which contains on average 60% to 70% of fissile isotopes (Pu239 and Pu241), and which makes up a little more than 1% of the used fuel; and lastly Fission Products (FPs) and Minor Actinides (MAs) which makes up the remaining 5% of the used fuel. In the PUREX process as it is implemented today at the La Hague reprocessing plant in France, FPs and MAS are considered as ultimate waste that are vitrified together. This reprocessing option is called “closed fuel cycle” because uranium and plutonium can be recycled to produce energy.

The choice between these two options remains open in several of the 31 countries (including Taiwan) in which at least one nuclear power reactor operates (at the end of the year 2018). These countries have taken the “wait and see” solution for the management of spent nuclear fuel. This unfortunately leads to the accumulation of SNFs at reactor sites or in a central interim storage facility. Some countries like Sweden, Finland, the United States and Canada (which has only CANDU-type nuclear reactors in operation) have decided to consider SNFs as a nuclear waste and thus to dispose of it permanently in a deep geological media (open cycle). Other large nuclear countries like France, Japan, Russia, and China have instead decided to reprocess their SNFs (closed cycle). **Table 1** below provides a summary of spent fuel management strategies in some OECD countries (NEA CSNI/R, 2015) (Russia and China are not OECD members so are not listed in this table).

France is by far the most advanced and experienced country in the world for reprocessing since it has chosen to reprocess all its spent fuel from the outset of its large nuclear power program in early 1970s (in 2019, there are 58 PWRs in operation in France, totaling 63 GWe of installed power). In total more than 36,000 metric tons (MT) of SNFs (content in heavy metal: MTHM) that have been reprocessed at the La Hague Reprocessing Plant (including SNF from foreign customers) which is equivalent to 3 years of SNF discharged from all the world’s reactors.

All countries which have to manage NW or SNF are signatories of the IAEA “Joint Convention on Spent Fuel and Radioactive Waste Safety” which entered into force in 2001 (IAEA INFCIRC/546, 1997). This Convention is the only legally binding international instrument to address on a global scale the safety of spent fuel and radioactive waste (RW) management. The goal is to achieve and maintain a high level of safety worldwide in SNFs and RW management through ensuring the availability of effective defenses against potential hazards, preventing radiological accidents and mitigating their consequences should they occur.

Reprocessing and recycling SNFs save natural resources

The most common industrial route used today to reprocess SNFs is the so-called “Purex” process. Schematically it consists in the shearing of fuel assemblies to allow for dissolution of the fuel matrix in nitric acid (no dissolution of metallic structures of fuel assemblies). This liquid mixture obtained after dissolution is treated with selective organic solvents to separate the Fission Products and Minor Actinides (NEA, 2012). The U and Pu are then chemically separated and undergo a specific treatment dependent on their future use. The fission products are processed to create a solid glass log for interim storage and the separated Uranium and Plutonium are stored for future fabrication to be recycled into fresh nuclear fuel.

Single recycling of Pu in nuclear reactors (sometimes called mono-recycling) is now commonly practiced in France for more than 30 years using what is called “Mox” fuels that are a mixture of plutonium and depleted uranium in a standard fuel assembly. This leads to an increase of more than 10% of global electricity production from the same amount of natural uranium extracted from the ground. In total near 300 metric tonnes (MT) of Pu have been recycled in the world using Mox fuels in LWRs. This corresponds to a production of electricity of about half of world’s nuclear power for 1 year (for the justification of this figure, see note 1 at the end of the text).

Even more energy can be achieved with the multi-recycling of Pu in LWRs (PWRs or BWRs). This has been demonstrated as feasible on an industrial scale and it will be implemented in France in the future (using a mixture of Pu and slightly enriched uranium, called Mix fuel). This should allow an additional increase of about 5% in global electricity production from a given

Table 1 Present spent fuel management strategies in some OECD countries.

Country	On reactor site interim storage	Centralized interim storage	Reprocessing	Direct disposal
Belgium	Yes	Yes (wet and dry)	Not any longer	Long term policy still to be developed
Canada	Yes	No	No	Future plans
Czech Republic	Yes	No	No	No
Finland	Yes	No	No	Yes
France	No	At reprocessing plant	Yes	No
Germany	Yes	Yes for some plants	Not any longer	Currently not but foreseen

Japan	Yes	Yes	Yes	No
Korea (Republic of)	No	Yes (Dry)	Under plan	Under review
Spain	Yes for some plants	Planned, dry	—	—
Sweden	No	Yes	No	Yes
USA	Yes	Under study in Texas and New Mexico)	No	Under study

quantity of natural uranium and should avoid the accumulation of spent Mox fuels. Both these options reduce the need to mine more uranium.

If plutonium could be recycled in fast neutron reactors (FNRs), operated in a breeding mode (which is a proven technology thanks to the successful operation of several power FNRs in the past), the increase in energy production could be enormous. Indeed, in that case the energy potential of natural uranium could be multiplied by a factor 100 making nuclear energy a sustainable source of energy because it is nearly independent of uranium natural resources.

Additionally, if full recycling of reprocessed uranium, after its re-enrichment, allows supplementary energy gain of 10% from existing uranium resources now in the fuel cycle.

In summary the recycling of U and Pu recovered from SNF in LWRs can reduce up to 30% natural uranium requirements to operate a nuclear reactor that produces the same amount of energy.

Reprocessing SNFs makes waste management easier and safer

Beyond the very significant natural uranium savings, reprocessing–recycling allows a substantial improvement regarding safety and management of NW. Indeed, as mentioned before, SNFs contain only 5% (or so) of highly radioactive ultimate waste (FPs + MAs), mixed with 95% of recyclable materials U and Pu, which are relatively very low in radioactivity. Therefore, it is much more efficient to deal with the two groups of nuclear materials separately as we now discuss.

A safer way to dispose of NW

In the Purex process, FPs and MAs are mixed together to form what is called “High Level Long-lived Waste” (HLLW) which are conditioned (at the atomic level) in a very robust and durable matrix which can last for hundreds of thousands years: The material created after mixing with Silica (sand) is a GLASS. This process is called vitrification (for details, see chapter 00611 of this encyclopedia). Many “natural analogs” demonstrate that this glass matrix is particularly resistant to water leaching for hundreds of thousands of years. It has been studied for more than 40 years during which it has been tested, qualified and manufactured for the sole purpose of efficiently confining HLLW.

This is not the case of a nuclear fuel assembly, which has been designed, tested, qualified and manufactured ONLY to produce energy in a reactor. It was not designed to confine HLW for hundreds of thousands of years. Therefore, if SNF are directly disposed of in a deep geological repository, they must be enclosed in a wear-resistant container which absolute tightness must be fully guaranteed during this very long period of time. This is not easy to demonstrate to safety authorities and it is not easy to convince the public that such human made structure is able to ensure total confinement of radiotoxic materials beyond 10,000 years. See Chapter 13.8 for the safety of disposal of HLW.

That said it is important to underline that the amount of HLLW generated by nuclear power is extremely small in comparison to the huge amount of energy that leads to the production of a small amount of HLLW. To give an example, for FP it is possible to make a simple calculation easily understood. Consider the energy released by the fission of an atomic nucleus which is converted to electrical energy in a nuclear power plant with an efficiency of about 34%. This fission gives rise to two FP which total mass is very close to that of the initial atomic nucleus. This allows a given mass of FP to be associated with a given amount of electricity in a rigorous and irrefutable way. For example, by taking an annual electricity production of a 1000 MWe nuclear reactor operating at full power for 1 year (that is 8.760 TWhe) we produce 1.095 tonnes of FPs per year. Furthermore, only 15% of these FPs, hence 164 kg, remain radioactive at the time of vitrification. They consist of 7 long-lived but low-level radioactive radionuclides (by definition!) and 2 radionuclides that have 30 years half-life, Cs137 and Sr90, which activity is reduced by more than a factor of a thousand after 300 years (divide by 2 ten times giving 1024). As for MA, which are all radioactive, the annual production of the reactor considered here is about 35 kg (this mass cannot be calculated “by hand” as for FPs, but of course data are available on this point). In total the amount of radioactive HLLW is less than 200 kg per year for this reactor running at full power all the time. This is an extremely small amount given the energy produced. Compared to this, a 1000 MWe coal-fired power plant releases nearly 300,000 tonnes of ash every year, including 400 tonnes of toxic heavy metals, arsenic, mercury, cadmium, including 5 tonnes of uranium 238 and 13 tonnes of thorium, 350 tonnes of soot and fine particles that escape into the atmosphere, and also 7.8 million tons of CO₂ and 10,000 tons of nitrogen oxide (NOX).

A drastic reduction of potential harmfulness of NW once disposed of in a final repository

Radiotoxicity of a radioactive element decreases over time due to its radioactive decay characterized by the radioactive half-life. A good indicator of the potential harmfulness of Radioactive Waste (RW) is the notion of “potential radiotoxicity” (PR) calculated at any given time. For a given mass of a radionuclide this indicator is obtained by multiplying two factors:

1. its effective dose coefficient by ingestion: The effective dose due to one Becquerel of activity of the radionuclide, that is of one nuclear radioactive decay per second (i.e. one disintegration or nuclear transformation per second). Effective dose is a measure of the hazard of the radionuclide provided by its radiotoxicity which accounts for type of radiation and tissue weighting factors as well as metabolic and biokinetic information. The unit of effective dose is the Sievert.
2. its specific activity at a given moment expressed in Becquerel per unit of mass.

Therefore, for a given mass of a radionuclide, PR is expressed in Sieverts (symbol Sv).

One would add the PR of all radionuclides contained in a RW (with the individual masses of each radionuclide contained in the waste) to have the overall PR of this RW being sure to include in PR calculations of the possible radioactive decay products (daughter) of each radionuclides.

If one takes the total amount of RWs contained in a repository one obtains what is called the “radiotoxic inventory” of the repository. In fact, the values obtained do not have much meaning in the absolute except perhaps for very small masses since the harmfulness thus calculated assumes that a person directly ingests this mass of waste. On the other hand, this PR can be compared with that of the mass of natural uranium (Unat) extracted from the subsoil that was used to generate a fixed amount of energy and thus a given mass of waste (FPs + MAs).

This mass of Unat depends mainly on the initial enrichment of the fuel which is determined by two parameters: (1) the “burnup” (or consumption) of the fuel (that is the total amount of energy extracted from one ton of uranium loaded into the reactor) and (2) the reload fraction of the reactor core (that is the fraction of fuel assemblies that is replaced at each reload, which generally is one third but can be also on half or one forth). For example, for an initial average uranium enrichment of 4.2% (average burnup of about 50 GWd/MTHM, load fraction one third) this mass of Unat which is used to make a ton of fuel (MTHM) is 7.84 t (for a tail enrichment of 0.2%). This comparison provides a valid benchmark for estimating the adverse biological effects on humans of waste since it is compared to the radioactivity of the Unat resource. For vitrified HLLW from reprocessing of SNFs these calculations show that the RP becomes lower than that of natural uranium after about 10,000 years.

Now, if SNF is considered as a nuclear waste and directly disposed of in a repository this achievement is entirely changed because of the presence of plutonium in SNFs. Indeed, the PR of Pu is by far the chief contributor to total PR of a SNF between few hundred years and 100,000 years or so (around 80% to 90%). This is illustrated clearly by Fig. 1 which shows the relative PR of SNF versus time (PR is normalized to one at each time).

Another important point to mention is that PR of a SNF becomes lower than that of natural uranium after 200,000 years or so which is 20 times longer than that of a vitrified waste.

In short, at a time when *recycling is key to human activities*, it is much more appropriate to *not dispose of plutonium* and use it to produce energy.

A significant reduction of volume of conditioned waste

The ratio of gross volumes of an SNF assembly to the volume of glass matrix enclosing FPs and MAs contained initially in this SNF is 3.85 (see note 2 at the end of the text for the calculation). This significant reduction in volume has two consequences.

1. During the interim storage period, SNF are stored either in large pools or air-cooled dry casks, either at-reactor or away-from-reactor in centralized facilities for long-term storage. The vitrified wastes from reprocessing are simply stored at the reprocessing plant site in air cooled steel tubes (shafts) enclosed in a concrete structure (building designated by the generic acronym ‘EV’ at the La Hague reprocessing plant (see Fig. 2). To this regard we can compare the volume of water in cooling pools which is around 2.5 m^3 – 2.8 m^3 /MTHM on average (see Table A3 of Reference NEA CSNI/R (2015)) whereas the volume of the EV concrete structure in which shafts are enclosed (see Fig. 2) is only 0.4 m^3 /MTHM.

It must be noted on this point that adequate cooling of SNFs stored in cooling pools dedicated to long-term storage of SNF may be lost either by malfunction of the pool cooling system (loss of cooling accident) or by loss of the pool water inventory (loss of

Fig. 1 Relative radiotoxicity of a spent fuel versus time – “Other” are mainly MAs.

Fig. 2 Storage facilities ('EV') for vitrified waste packages (VWP) - La Hague reprocessing facility – France.

coolant accident). This safety issue must be assessed very carefully: see Reference. (NEA CSNI/R, 2015). This issue is not as acute for the long-term storage of vitrified waste since simple air-cooling systems are enough to remove the heat that they generate. After about 6 to 7 years the system can operate using only natural convection.

2. Prior to geological disposal the SNF must be enclosed in a rugged casks designed to withstand a multitude of possible degradation mechanisms (See Chapter 13.8) The glass matrix is simply enclosed in a light protective steel case in which the mixture of melted glass with FPs and MAs is poured. To make a meaningful comparison in term of volume (and weight) between the two options (disposal of SNFs versus disposal of corresponding vitrified waste), we can take the example of the so-called "KBS3" Swedish geological repository which is one of the most advanced project in the world for final disposal of SNF, located in Forsmark site (140 km north of Stockholm). In this project, the SNF container is a large copper cylindrical canister which accommodates 4 PWR SNF assemblies which contains 1.840 MTHM. Its overall dimensions are 1050 mm of external diameter and 4835 mm of external height (thickness of copper walls is 50 mm); hence a volume of 1.33 m³. Its total weight with the 4 PWR SNF assemblies inside is 26,800 kg (SKB report TR-10-14, 2013). The corresponding equivalent volume of vitrified waste package would be 0.23 m³ with a weight 631 kg. The volume ratio between the two options is thus 5.8 and the weight ratio is 42. This is again a large volume reduction (and a very large weight reduction). It must be mentioned that the real benefit of such reduction in volume for the final disposal depends on many other parameters such type of geological media, architecture of the disposal facility, cooling time of waste before its disposal in the repository and design of SNF canister.

Partitioning and transmutation (P&T): a further step towards reduction of ultimate nuclear waste (NW) burden

Long term radiological impact of NW disposal depends on the amount of long-lived radioactive elements disposed. These elements are mainly the 7 long-lived Fission Products (LLFP), Tc99, I129, Se79, Zr93, Pd107, Cs135, Sn126 and the main isotopes of the 3 Minor Actinides, Am, Cm and Np. To this end, the starting point is to separate (partition) them and, once they are separated to "destroy" them individually via appropriate nuclear reactions. To achieve this, the only practical way known today is to get them to absorb a neutron which either transforms them into another element with a shorter half-life (or even a stable element) or to "break" them through the fission process. This process is called "Partitioning and transmutation", in short P&T.

For a better understanding of this section, it helps first to recall some important characteristics of actinides, which are shown on Table 2.

As stated before, one can see that plutonium is the "major" actinide" in a SNF in terms of mass with a total of 11.2 kg Pu per ton of heavy metal (THM) (> 1%). Dominant minor actinides are Np237 and Am241 (and, in a lesser extent, Am243).

The long term impact of geological repositories for NW

Let's first recall that deep geological repository in an appropriate media is unanimously recognized as the best solution for final disposal of HLLW (Kadak, 2021). Thank to numerous safety studies carried out in the world this mode of isolation of

long-lived radioactive waste has proved to be highly secure and environmentally sound subject to the selection of an adequate geologic media. In particular this media must stable for at least several hundred thousands years and away from any significant circulation of free water in order to ensure radionuclide radiotoxicity has become sufficiently low (due to natural radioactive decay) before their possible migration to the surface could constitute a danger to living species and the environment. Another criterion generally taken into account in choosing a storage site is that of minimizing the risk of human intrusion once the site becomes unmarked (i.e., the site is released for public use after the monitoring period). To achieve this, waste must be disposed of in a repository as deep as possible (typically at least 200 or 300 m below the surface) and as far away from any natural resource as possible.

Almost all host formations (granite, clay, salt) feature excellent confinement properties in the long term for HLW for the normal evolution of geologic repositories, that is for the future evolution of the disposal system under the predicted (expected) thermal, hydrological, chemical and mechanical conditions based on the knowledge of the past evolution of these geological conditions. Hence, calculated dose levels at the surface are significantly lower than the most stringent regulatory limits and natural radiological background. This very small long term radiological impact is mainly due to the soluble long-lived FPs (LLFPs) such as Tc99 which half-life is 211,000 years (although sparingly water-soluble as metal or oxide in reducing conditions of deep aquifers), and I129, which half-life is 15.7 million years for SNF disposal. One may note in passing that there are only tiny amounts of I129 in glass because iodine is highly volatile at the temperature of vitrification (1100 °C) and thus cannot be incorporated in the glass with other FP. It is therefore released into the environment at the La Hague plant (under stringent regulatory limits and strict control) mainly in the NaI liquid form (> 96%) in sea water where it is diluted with natural iodine. Because of this dilution and from the fact of its very low specific activity (due to its very long half-life) the radiological impact of this dispersion in marine environment is practically nil.

Unlike long-lived fission products (LLFPs), MAs are almost insoluble in underground waters and they migrate extremely slowly in reducing conditions prevailing in deep geological media. Consequently, MAs have practically no radiological impact even in the very long term under normal evolution of a NW repository. Nevertheless, the presence of minor actinides in the waste is the main source of long-term potential radiotoxicity (PR): after three centuries, nearly 99% of the PR of the vitrified waste forms currently produced will be due to the presence of americium, curium, and their decay products. The share of the different MAs in this PR is illustrated by the curves of the Fig. 3A drawn from (Magill et al., 2003) and Fig. 3B drawn from (CEA, 2012a) (these figures have been reformatted for the purpose of this article).

These curves show that americium is the dominant contributor to the PR of MAs from 100 years and up to 100,000 years, mainly because of its isotope Am241 whose half-life is 433 years (its radioactive daughter being Np237) and which proportion by mass is 2/3 of that of the total of all isotopes of americium and curium combined. The intrinsic PR of curium, which proportion by mass is less than 10% of americium plus curium, is always much lower than that of americium. The PR of curium falls below that of natural uranium after few hundred years. As a matter of fact, the major isotopes are Cm243, whose half-life is 30 years (its radioactive daughter being Pu239) and Cm244, whose half-life is 18 years (its radioactive daughter being Pu240). As for neptunium (which has only one isotope Np237), it is clear that its contribution is much lower than that of other MAs up to about 100,000 years,

Fig. 3 (A) Actinide radiotoxicity in spent PWR fuel vs. time. Results are grouped by element present after 6 years of cooling and the radiotoxicity of each isotope of an element includes that of their radioactive daughters. (B) Relative radiotoxicity as function of time normalized to 10 at 10 years: effect of P&T on americium only and on americium + curium.

a date after which total PR remains lower than the reference radiotoxicity of natural uranium in equilibrium. This is due to its very long half-life (2.144 million years) and to the low specific radiotoxicity of its radioactive daughter, U233 (half-life 160,000 years).

Performance assessment studies

To obtain a quantitative evaluation of potential releases of radioactivity from a disposal facility into the environment and to assess the resultant radiological doses, repository “performance assessment” (PA) studies are carried out. PA can refer to the process, model, or collection of models used to estimate future doses to human receptors. Typically, a PA is conducted to demonstrate whether a disposal facility has met its performance objectives.

Let us just note here that these studies allow not only to estimate the long-term radiological impact of NW disposal but also to assess the potential benefit of the reduction of amounts of long-lived radioactive elements on this impact. Before examining the technical feasibility of P&T, let’s discuss its potential benefits on geological repositories.

Effect of P&T of NW on sizing of geological repositories and on its long-term impact

We have seen above that the radiological impact of a NW repository in the very long term (> hundreds of thousands years), if any, would come only from Long-Lived Fission Products (LLFPs), that cannot be easily transmuted at industrial scale (and even cannot be transmuted at all for several of them). Fortunately, this impact is so low under all credible scenarios that this very partial transmutation would have practically no effect on this radiological impact.

The situation is quite different for MAs. As a matter of fact, lessons learned from numerous PA studies carried out in the past have shown that advanced fuel cycles with P&T of MAs can offer potential benefits to NW disposal in geological repositories. More specifically, two main advantages can be anticipated from P&T of MAs:

- Reduction the potential harmfulness arising from ingestion of the radioactivity of MAs present in long-lived high-level waste in the so-called “human intrusion” scenario (though very unlikely scenario) or in scenarios considering an unforeseen change of the geochemical conditions favoring actinide migration, e.g. establishment of an oxidizing environment in the repository
- Reduction of the heat load (“thermal load”): larger amount of wastes can be stored in the same repository (depending on the host formations). Studies carried out in the frame of the European “Red Impact” project ([RED IMPACT, 2006](#)) have shown for example that removing a significant part of MAs from waste allow a reduction of the emplacement galleries length up to a factor 3–6 after interim storage cooling time of at least 50 years for deep geological repositories in clay and hard rock formations.

As for the first point (potential radiotoxicity PR) we have already indicated that Am241 is the major contributor (see [Fig. 3A](#) and [B](#)). We have also observed on these curves that P&T of both americium and curium would diminish the PR by a factor of 100 after a few centuries up to few thousand years and a factor 15 to 20 beyond (up to 100, 000 years or so). If full P&T was implemented for all MAs (Am, Cm and Np), i.e. assuming no loss of material during reprocessing, the total PR of vitrified waste would fall to a level equivalent to that of all the uranium mined for fuel fabrication today in less than 500 years (because in that case the remaining PR would be only that of LLFPs).

As for the second point (heat load) the contribution of FPs and MAs are plotted on [Fig. 4A](#) drawn from ([Wigeland, 2006](#)) for spent fuels and [Fig. 4B](#) drawn from ([CEA, 2012a](#)) for vitrified waste.

For spent fuels ([Fig. 4A](#)), the decay heat is mostly from actinide elements after 60 years, with the important actinide elements being plutonium and Am241. Beyond 200 years, the decay heat is caused entirely by isotopes of plutonium and americium, out to at least 10, 000 years. For vitrified waste ([Fig. 4B](#)), Am241 becomes dominant (> 50%) after about 80 years and then it becomes more and more the dominant contributor to the total decay heat: 70% at about 120 years and almost 100% after 300 years. Yet, the heat released from vitrified waste packages determines to a large extent the design of repository disposal cells: the lower the heat load in the waste, the higher the disposal density of the repository. Removing MAs from the final waste and providing a prior interim storage period long enough to allow significant radioactive decay of the short-lived fission products could thus significantly reduce the size of the repository. To this regard, the French agency for radioactive waste management (ANDRA) estimated a gain by an order of magnitude on the footprint of the disposal cells for vitrified waste packages in the clay disposal concept currently envisaged in France (CIGEO project) for a 120 years interim storage period before their emplacement in the repository. This would represent an overall footprint reduction for the entire repository, including intermediate level waste storage and access infrastructures by about a factor of 3 (see Reference [CEA \(2012b\)](#)).

Feasibility of P&T

Numerous studies have been carried out on P&T issues in most countries having a significant nuclear program, in particular in France and some other European countries but also in the USA and Japan (see for example Reference [OECD \(2011\)](#) pages 39 to 59 for an overview of these studies).

These studies (theoretical and experimental) have shown that transmutation of LLFPs by neutron irradiation is ineffective for the majority of them. Nevertheless, there has been some examination of the potential for treating Tc99 and I129, which appear to be the only LLFPs that can be transmuted in reactor systems. Transmutation of Tc99 is possible if it is present as a metallic target, since the transmutation product is inactive Ru100. However, due to the very small thermal cross-section of 20 barns, a high thermal neutron flux is needed as is a high loading in the reactor with an optimized moderator to target radius. Furthermore, multi-recycling is needed to achieve a high rate of transmutation of Tc99. Another fact which makes the transmutation of Tc99 less interesting is that PA studies have shown that the chemical form of Tc in deep geological conditions makes it much less soluble in water, thus not too mobile (Reference [CEA, 2012a](#)).

Transmutation of I 129 is a very difficult task because it has a moderate to small thermal cross-section (27 barns) and no thermally stable iodine matrix has been found. In addition, two conflicting safety requirements must be fulfilled: on the one hand, the confinement of the iodine compound in the target capsule during irradiation and, on the other hand, the discharge of the produced xenon. A vented capsule with an iodine filter needs to be investigated. The upscaling of such complex irradiation procedures to industrial quantities is not obvious. More detailed technical information on P&T of LLFPs can be found in Reference [OECD \(2006\)](#) pages 88 to 100 and [IAEA \(2004\)](#) pages 97 to 100.

Vitrified waste package from co-reprocessing of UOX spent fuel (85%) and MOX spent fuel (15%)

Fig. 4 (A) Key contributors to the decay heat (residual heat) in spent PWR fuel irradiated to 50 GWd/MTIHM. Note that plutonium isotopes are not present in vitrified waste except Pu losses which are very small ($< 0.1\%$) but more importantly as decay products of curium isotopes which are produced in a very low amounts and therefore which does not contribute significantly to the total decay heat of vitrified waste: see (B) Dominant decay heat (residual heat) contributors in vitrified waste. (A) Wigeland A (2006) Separation and transmutation criteria to improve utilization of geologic repository. *Nuclear Technology*. 154. (B) CEA, Nuclear Energy Division (2012) *Séparation et transmutation des éléments radioactifs à vie longue*, Tome 2.

Studies of the partitioning of MAs have been carried out (and are being continued) in France mainly by the CEA (in cooperation with EDF and other industrial actors) within the framework of the laws governing research and management on NW. This important program includes:

- Experimental test at laboratory scale on actual spent fuel samples (several kg) of the processes that have been developed by the CEA to recover minor actinides using new extractants that are both selective and resistant. Several options were considered,

corresponding to various possible recycling routes: group separation of all the actinides for homogeneous recycling, sequential separation for minor actinide recycling in core blankets, separation of americium alone, etc. The observed performance was excellent (recovery yields above 99%) and additional tests were carried out to approach the operating conditions at industrial scale. The results are very encouraging (especially with regard to the endurance of the molecules involved) and are very promising for possible commercial application of the concepts investigated.

- As for transmutation, results acquired since 2005 by the CEA have shown that the minor actinides could be efficiently transmuted only in a fast neutron spectrum (whether in power reactors or in dedicated devices). This was confirmed later by analyzing irradiation in the Phenix fast neutron reactor in homogeneous mode ("Superfact" experiment) and heterogeneous mode (irradiation of pin segments containing americium-bearing pellets on various media).

In the frame of this article we can only provide a brief summary of the main outcomes of this program.

Considering the previous discussion on radiotoxicity and decay heat, these studies confirm that the first target for a transmutation strategy could be americium since it has the most limited impact on existing recycling operations. On the other hand, neptunium is seen as a secondary candidate for transmutation due to its very long half-life and low activity. Curium transmutation is virtually ruled out due to the high activity of curium isotopes. As a matter of fact, its transmutation in heterogeneous mode (target fuel assemblies) is almost impossible even if it is mixed with americium especially because of its intense specific heat. Its recycling in homogeneous mode is subjected to severe constraints (fabrication and transport of fuels) which are an order of magnitude greater than for recycling americium, because of its very high radiation level. In particular, curium is an intense source of neutrons (from spontaneous fissions of even isotopes): see [Table 2](#). Furthermore, transmutation of curium is a slow and complex process that generates higher isotopes of which Cf252 that can be extremely troublesome due to its very high specific neutron emission rate. In one word, it seems that disadvantages of the P&T of curium far outweigh its potential benefits.

Another result of these studies is that homogeneous recycling of MAs in fast neutron reactors may affect some core safety parameters. Recycling them in core blankets (heterogeneous mode) leads to difficulties in fabrication and handling of assemblies, before and after irradiation in the reactor. P&T of MAs at industrial scale could also increase occupational doses of workers (this point has been particularly addressed in Reference [Grenèche et al. \(2001\)](#)). More generally, it could probably increase the risk associated with the industrial implementation of the entire P&T process (for example consequence of a failure somewhere in one of the facilities or equipment dedicated to P&T). It could also increase the overall cost of the fuel cycle. To this regard, the CEA assessment is that P&T would increase the levelized cost of electricity from 5% to 10% depending on various options (homogeneous or blankets, minor actinides or americium alone). This extra cost is nonnegligible and must be carefully considered against expected benefits of P&T, including a greater social acceptance of nuclear waste disposal (this point is discussed in more details in Reference [Grenèche et al. \(2006\)](#)).

Conclusion

Recycling of Plutonium and Uranium in light water reactors can increase energy production from natural uranium ore by 30%. If fast breeder reactors are used, nuclear energy can be a sustainable long-term energy source. Indeed, fast breeder reactors are able to use the energy potential of the totality of natural uranium (100%) by transforming most of the U238 into plutonium, whereas current reactors use barely 0.5% of this natural uranium to produce nuclear energy.

Recycling of used nuclear fuel has already demonstrated a significant reduction of the volumes and long-term radiotoxicity of nuclear high-level waste through the reprocessing of 37,000 tonnes of spent LWR fuel to recycle the plutonium and uranium. These closed fuel cycles provide the opportunity to partition classes of nuclear waste and to manage each class in a separate waste form according to its individual characteristics. Advanced waste management strategies include transmuting of selected nuclides, cost effective decay heat management, flexible interim storage, and customized waste forms for specific geologic repository environments. These strategies hold the promise to significantly reduce the long-lived radiotoxicity of waste destined for geological repositories by at least an order of magnitude. Such reductions, and the ability to optimally condition the residual wastes and manage heat loads, will permit more efficient use of repository capacity and further enhance overall safety of the final disposal of radioactive wastes.

Nevertheless, whatever procedure is implemented to manage waste streams from different back-end fuel cycle options including advanced processes for P&T of long-lived radionuclides, a deep geological repository to host HLLW is unavoidable and it is a safe way to dispose of them.

Notes

1. This equivalence is obtained using the French case for which about 10 MT of Pu is recycled every year in MOX fuels (in 24 PWRs of 900 MWe power each) thereby providing 10% of its 400 TWhe nuclear electricity (rounded up), that is 40 TWhe. Since nuclear power in the world produces about 2500 TWhe per year (2563 TWhe exactly in 2018), half of this production (1250 TWhe) can be produced with 300 MT of Pu recycled in MOX fuels (result obtained with a single rule of three). Another way to obtain the same result is to consider directly the energy released by one fission of a Pu239 atomic nucleus (210 MeV) and suppose that only half of the 300 MT of Pu can fission (because of isotopic composition of Pu and because incomplete fuel

burnup). The exact calculation of plutonium mass to produce 1250 TWhe gives 156 MT, which is coherent with the previous result (about half of the 300 MT).

2. We take the example of a standard fuel assembly of a typical 900 MWe PWR which fuel pins (tight zircaloy tubes) containing enriched uranium in the form of oxide are arranged in a 17×17 tubes square array. The square cross-section is 462 cm^2 and height is 4 m, hence a volume of 0.185 m^3 . We also take a standard average burn-up of 45 gigawatt-days per metric tonnes of heavy metal (HM) loaded (GWd/MTM) which leads to a content of 21.5 kg of FPs and 0.6 kg of MAs in the corresponding spent fuel assembly. The initial mass of HM in this fuel is 460 kg of 3.7% enriched uranium. If this SNF is reprocessed using the Purex process (as implemented in France at the La Hague plant), the glass matrix obtained from vitrification contains 16.5% of FPs and 0.5% of MAs *w/w* and has a density of 2.67. Therefore, the vitrification of $(21.5 + 0.6) = 22.1 \text{ kg}$ of (FPs + MAs) from one SNF assembly leads to 130 kg of glass, that is a volume of 0.048 m^3 of glass. Hence the *ratio* of 3.85 between the gross volume of an SNF assembly and the corresponding glass matrix. If we take into account the protective steel case and gripping device of the standard vitrified waste package containing 400 kg of glass (that is a volume of 0.15 m^3) the volume of the package is in fact 0.18 m^3 and this ratio is somewhat less: 3.2. We do not consider here the other category of nuclear waste from reprocessing that is “compacted waste.” This waste result from the compaction of metallic structures of the fuel assembly (cladding hulls, end pieces (top and bottom nozzles), grid spacers and some other metallic components like springs, etc.) produced by the shearing of the SNF at the head end of the process (before dissolution of the fuel matrix). This is because they are *not* high level waste and almost *not irradiating* (their radioactivity is at least 100 times less than that of vitrified waste and is mainly alpha type of radiation) which does not generate heat (less than 10 watts per package). Consequently, they can be managed in much more simple way than vitrified waste whatsoever for the duration of interim storage or for final disposal.

Introduction

One of the key social issues affecting public opinion on the use of nuclear energy is that associated with nuclear waste disposal. The public's primary concern is reactor safety but very quickly comes the question: "What are you going to do with the waste"? In the United States, this issue has significant technical and political ramifications. In a 1957 report by the National Academy of Sciences entitled "The Disposal of Radioactive Waste on Land" (Hess, 1957), Committee of Waste Disposal of the Division of Earth Sciences recommended that high level nuclear waste (primarily used fuel from nuclear reactors) could be safely disposed of in stable geological formations. In 1970, the US began searching for possible disposal sites based on this recommendation. This same recommendation was followed by other nations of the world. Table 1 summarizes the national waste disposal efforts of many nations some of which are still in the research phase and others are in the development phase. What is interesting in this table is the different geologic media being used by a country depending on their particular geology (Wikipedia, 2019; International Atomic Energy Agency, 2018).

What follows is a discussion of the evidence of the feasibility of safe geological disposal of radioactive materials using as examples natural nuclear reactors and an existing United States nuclear waste geological disposal site in New Mexico. A summary of the US licensing studies justifying the safety of the proposed Yucca Mountain High Level Waste (HLW) site and the Finland's HLW disposal project which is now under construction is provided.

Reactors in nature

The real question is can nuclear waste be safely disposed? Perhaps the best answer to this question is found in nature. More than 2 billion years ago, natural uranium was of sufficient concentration in U-235 and under the right geological conditions was able to sustain a natural fission chain reaction, i.e. a natural nuclear reactor (Stuchbery, 2021). The concentration (enrichment) of U-235 in natural uranium 2 billion years ago was about 3% which is about what is necessary for a fission reaction to occur when in the presence of water. This reaction produces byproducts which are referred to as fission-products or nuclear waste. The half-life of U-235 is about 700 million years during which time about half of the U-235 will have decayed away to other non-fissile isotopes. Thus, over 2 billion years, the concentration of uranium-235 was reduced from about 3% to today's concentration of 0.72%. Many of the fission products are also radioactive and their natural decay is an important feature of nuclear waste since its radioactivity or hazard decreases with time. After about 10,000 years the radioactivity level from this waste is about the same level as natural uranium.

To date, 15 such natural reactors have been identified in a uranium mine in Oklo, Gabon, South Africa (Hess, 1957; Smellie, 1995; Cowen, 1976). This site has been studied for many years to determine how such a natural reactor might have been possible. Good summaries of how the natural reactor worked are described by Bressen (2018) and Meshik (2009). In essence, given that the concentration of U-235 was about 3% and sufficient water was present with no strong neutron absorbers that might capture the natural neutron emission from uranium, the "reactor" had the needed moderation to slow down the neutrons emitted from uranium fission allowing for fission-chain-reaction to take place. What happened when the "reactor" went critical, namely had a self-sustaining nuclear chain reaction, was the water was heated by the energy released as a result of the fission process and boiled off. This essentially shut the reactor down. Once cooled down and water returned, the reactor was restarted repeating the boil off cycle. This on/off cycle continued for about a million years until there was not a sufficient concentration of uranium-235 left since it

was consumed by fissioning or reduced by natural radioactive decay. The accumulation of fission products also interferes with sustenance of a chain reaction.

The Gabon site was used to study what happened to the fission products over time. This is a critical issue for safe nuclear waste disposal since the goal is to understand how these byproducts may have migrated from this underground mine to the environment. The good news is that the studies show minimal migration from the original site of the fission reaction 2 billion years ago. In fact, one of the key waste isotopes of concern is plutonium produced by neutron capture in U-238 (which makes up over 99% of the uranium in the earth today, and ~97% 2 billion years ago). Analysis has shown that the plutonium moved less than 10 ft away from its original creation some 2 billion years ago (Kaushuk, 1976). This natural analog provides scientists great confidence in geological disposal options under consideration. Fig. 1 is a photograph of one of the Oklo natural reactors in the mine.

What is nuclear waste?

High level nuclear waste comes from the operation of reactors, nuclear reprocessing (recycling) plants, nuclear weapons production facilities, nuclear ships and submarines operated by naval forces and wastes that come from nuclear accidents such as Fukushima, Chernobyl and Three Mile Island. It is called high level because of its intense radioactivity that requires special shielding to prevent human exposure.

What people commonly refer to as nuclear waste as it affects the social issue of the use of nuclear energy is that associated with the used fuel that comes from the nuclear reactor after about 4 years of operation. This ceramic uranium fuel pellet is contained in tubes of zirconium metal (fuel rods) about 12 ft tall in box like assemblies as shown in Fig. 2 below. The composition of the used

Fig. 1 A natural nuclear reactor in Oklo, Gabon. Uranium oxide remains are visible as the yellowish rock. Photo credit: Robert D. Loss/APOD.

Fig. 2 Schematic of a nuclear fuel assembly. Source: <https://public-blog.nrc-gateway.gov/2015/03/12/dry-cask-storage-the-basics/>

fuel, its radioactivity and its heat generation as a function of time following removal from the reactor core are described in Glatz (2021).

At the reactor sites, this used fuel is stored in 40 ft deep water pools as shown in Fig. 3, which remove the heat generated in this fuel due to the radioactive decay of its fission products and provide shielding from any radiation emitted from the used fuel. Once the used fuel has cooled down sufficiently not requiring anything but natural air cooling, the used fuel is transferred into dry cask storage facilities, as shown in Fig. 4, that provide adequate air cooling, shielding against radiation and physical protection (Nuclear Regulatory Commission, 2016).

Fig. 3 Fuel assembly in a spent fuel storage pool at reactor site. Source: ansnuclearcafe.org.

Fig. 4 Dry cask storage of used fuel (naturally cooled by vented air in bottom). Source: <https://www.nrc.gov/reading-rm/doc-collections/fact-sheets/dry-cask-storage.html>

The used fuel is very radioactive and needs to be shielded by concrete or metal casks. The good news is that the quantity of this used fuel is very small. As an example, all of the spent fuel produced by all the US operating reactors since 1950 can be placed on a football field 10 ft deep. This quantity of material can easily be stored in a single geologically mined cavity in the earth.

At present, many of the spent fuel storage pools at operating reactors have reached their maximum capacity and utilities are building dry cask storage facilities at their sites pending the Department of Energy's readiness to start taking the spent fuel from the sites either to an underground repository or a centralized interim storage facility which also has not been built. By contract and by law, the United States government is obligated to remove and dispose of used nuclear fuel from nuclear plant sites.

Waste isolation pilot plant—The US first geological disposal site

In the United States, nuclear waste disposal efforts initially focused on underground salt domes that have been stable for millions of years. Early efforts in siting a high level waste repository focused on Lyons, Kansas which was ultimately found unsuitable due to water in-leakage. Despite this early failure, the United States was able to site an underground geological disposal site in bedded salt for plutonium contaminated nuclear waste from US nuclear weapons facilities.

The United States has an operational geological underground repository for nuclear waste in New Mexico. The Waste Isolation Pilot Plant (WIPP) has been in operation since 1999 for transuranic¹ (TRU) (primarily plutonium) contaminated wastes in an underground salt deposit (Energy, 2019; Environmental Protection Agency, 2020). The nuclear wastes disposed in the WIPP consist of wastes which are byproducts of the nation's nuclear weapons and defense programs. These wastes include plutonium contaminated tools, rags, sludge, and other materials that have been contaminated with radioactive materials.

In 1974 the Atomic Energy Commission selected a bedded salt deposit near Carlsbad, New Mexico for disposal of TRU wastes. The bedded salt was created 250 million years ago from an ancient Permian sea bed in an underground 2000 ft thick salt deposit. After years of study, the US Environmental Protection Agency licensed WIPP for safe long term disposal of TRU wastes. The state of New Mexico and the US Department of Energy reached an agreement to allow for the construction, operation and oversight of WIPP for its operating lifetime.

A picture of the WIPP from the surface is shown in Fig. 5 with Fig. 6 showing a mined salt cavity and barrels of plutonium and other TRU contaminated wastes. As can be seen in the figures, the TRU waste is contained in barrels which are contact-handled meaning that the radioactivity is very low. WIPP also has remote-handled TRU waste which requires special handling. As of January 2017, 170,000 containers plus other boxes and overpacks amounting an equivalent of 450,000 55 gal drums have been disposed of in the WIPP facility.

The value of salt as a disposing medium is that it has been stable for millions of years, contains no flowing water and is self-sealing in that over time the salt encapsulates the waste packages. One of the challenges is that periodically, the operating shafts have to be re-mined to keep the shafts open due to the creeping of the salt.

The problem of disposing high level nuclear waste

The political challenge of nuclear waste disposal is dominated by opposition to siting a nuclear “waste dump” enabling politicians to use the waste issue to help their election prospects especially in the United States. While this may not be universally applicable in other countries, public fear and apprehension of nuclear waste disposal drives the political opposition to siting. In the United States after years of study for possible sites by the Department of Energy, the US Congress passed the Nuclear Waste Policy Act of 1982 and amended in 1987 ([United States Law, 1982](#); [Department of Energy, 2004](#); [O'Donnell, 2019](#); [US Congress, 1987](#)) which ultimately selected the Yucca Mountain site in Nevada as the primary location for disposal of used fuel subject to successful licensing. This law is still the law of the land. Yucca Mountain is approximately 90 miles northwest of Las Vegas on the former nuclear weapons testing site. It is a relatively desolate area with very little rainfall. A picture of the Yucca Mountain site is shown in [Fig. 7](#). The potential repository would be about 1000 ft below the mountain in a series of mined tunnels.

Part of the law mandates the collection of funds from nuclear generating stations based on the amount of electricity generated by the plants. This fee is \$0.001 per kilowatt-hour of electricity which is to be used to fund the cost of building and operating a high level waste disposal site. Up to 2018, about \$41 billion has been collected for nuclear waste disposal ([General Accounting Office, 2011](#); [DOE Office of Environmental Management, 2019](#)). By 2011, the Department of Energy and many of the nation's national laboratories spent \$15 billion to study the Yucca Mountain site and other possible sites.

Following the determination of site suitability in 1998, the DOE proceeded to prepare a license application to the Nuclear Regulatory Commission (NRC) for construction and operation of the waste disposal site. In 2008, the DOE submitted its application to the NRC for a detailed review. Unfortunately, once the review was nearly complete, Senator Reid of Nevada, who was the majority leader of the Senate at the time, withheld funding from the NRC to conduct hearings on the safety of the project. The NRC did issue a Safety Evaluation Report ([Nuclear Regulatory Commission, 2010](#)) for the entire project which could have led to a construction permit and eventually an operating license. The NRC's conclusion of the Safety Evaluation Report was:

On the basis of the information provided in the license application and the commitments specified in the Safety Evaluation Report (SER), Volume 1, Chapters 1–5 and Appendix, the NRC staff concludes that the Yucca Mountain repository meets the following requirements of 10 CFR Part 63² with respect to a construction authorization.

²10 CFR 63 outlines the requirements that the repository must meet to be licensed for construction and operation.

Fig. 7 Aerial view of Yucca Mountain looking south. Showing the desert environment and remote location. Source: <https://www.energy.gov/sites/prod/files/edg/media/SER.PDF>

The Obama administration subsequently ordered the Department of Energy to withdraw the application essentially canceling the project (Northey, 2011). However, the law of the land still requires that the repository be built at Yucca Mountain. At the present time, no work is being done at Yucca Mountain.

United States Yucca Mountain high level waste repository

What follows in this section is a short discussion of the technical viability of the Yucca Mountain site based on the license submittal to the NRC showing that safe geological disposal is possible. Prior to its suspension, the Yucca Mountain Repository site had been studied for over 20 years. We use the Yucca Mountain NRC licensing review of the safety of deep geological disposal and an example of why nuclear waste can be disposed of safely. While the licensing was not complete, much of the technical work was justifying the safety of the disposal option.

One of the major accomplishments of the project was the completion of the Exploratory Studies Facility which started in late 1992 and was completed in 1997. The large tunnel and side drifts provided scientists and engineers to conduct studies of the hydrology and geology of the mountain to support the design and licensing application for construction of the repository (see Fig. 8).

Fig. 8 Photograph of the tunnel boring machine in Yucca Mountain. Source: <https://www.energy.gov/sites/prod/files/edg/media/SER.PDF>

The studies leading up to the license application for the Yucca Mountain High Level Waste Repository and the review by the Nuclear Regulatory Commission of this application form the basis for stating that high level nuclear waste can be safely disposed. The basic design of the Yucca Mountain repository is based the National Academy of Science's 1957 finding that the best means for long term disposal of HLW is in geological media deep underground. Based on this fundamental finding, Yucca Mountain was chosen as the primary site in igneous rock 2000 ft underground in an engineered series of tunnels designed to deal with events including water ingress, seismic, climate changes, volcanic disruptions and human intrusion events that may occur for the licensed period of 10,000 years. Analyses were performed even out to 1 million years to check for any outlier events or processes that might compromise the geological isolation of the nuclear waste. The design calls for manufacturing spent fuel canisters in specially designed casks. Although the basic concept relies on the fundamental geology to contain the radioactive materials, the Department of Energy chose to add additional engineered barriers to prevent water from attacking the waste packages and ultimately reaching the used fuel pellets. This system was called the Engineered Barrier System (EBS) to provide for a defense in depth approach to system safety. The EBS mitigates any possible corrosion of the waste packages which contain the used fuel under a multitude of possible events that could disrupt the repository.

The basic layout of the Yucca Mountain repository is shown on Fig. 9 (Department of Energy, 1998). As can be seen, the design calls for a series of 100 placement tunnels about 73 miles in total length 2000 ft underground. Each tunnel would hold about 100 waste packages containing the used fuel in specially fabricated casks designed to provide radiation shielding and corrosion protection. One such series of tunnels would provide disposal of 70,000³ tons of used fuel from operating reactors. This value could be expanded since there is adequate additional space available to store all of the nation's used fuel for the life of all operating nuclear plants.

The studies by the Sandia National Laboratory, the lead national laboratory for the Department of Energy, and other national laboratories including the US Geological Survey culminated in the submission of a license application for the construction of the repository in 2008. The NRC reviewed the license application containing the results of numerous studies and analyses showing that the repository could be safely built and operated. Opponents of the repository filed numerous contentions requiring resolution by the Atomic and Licensing Board after public hearings. Unfortunately, due to the action of Senator Reid of Nevada, these hearings

Viability Assessment: Repository Reference Design Concept (Volume 2)

³The 70,000 tons is a law limit at present.

were never held since under his leadership Congress withheld monies for this review which have yet to be restored continuing the political stalemate on siting a repository.

The safety case for the Yucca Mountain high level waste repository

A summary of the findings of the NRC review is presented below showing that the repository could be safely operated for the 10,000 year below the post closure individual protection standard as defined in 10 CFR 63.311 (Nuclear Regulatory Commission, 2009) according to the analysis. These results are documented by the “Total System Performance Assessment Model and Analysis for the License Application” (Sandia National Laboratory, 2008; Department of Energy, 2002). The key challenge for the design of an underground nuclear waste repository is demonstrating that over the period of 10,000 years that the radioactive materials contained in the fuel, the canisters, and metal overpack casks will not reach the habitable environment over that period. The analysis focuses on possible mechanisms that can deteriorate the protective canisters and eventually degrade the metallic fuel pins allowing the fission products (so called waste) to somehow migrate to the surface through water pathways that are deep underground. Thus, site selection is very important in that sites should be selected that have minimal rainfall such as the Nevada desert.⁴ Additionally, sites should also have minimal seismic or volcanic activity that could create direct pathways to the environment. These are likely reasons that Congress selected the Yucca Mountain site among numerous alternatives.

One of the first major studies completed prior to continuing with a formal license application to construct the repository at Yucca Mountain in the Nevada desert was a viability assessment prepared by the nation’s national laboratories. This viability assessment was the first study that preliminarily demonstrated that subject to more detailed studies, Yucca Mountain was acceptable for further study and development.

This viability assessment modeled all possible mechanisms that could lead to the migration of the radionuclides into the environment as shown on the figure below. Since water is a very important parameter affecting possible degradation of the waste packages and migration into habitable environment, modeling climate, infiltration, water transport, package degradation, and movement of any dissolved waste products into the human biosphere as illustrated in Fig. 10.

As can be seen, the analysis attempts to consider all possible mechanisms for container failure due water pathways which may cause corrosion and eventual package failure. Once the package fails, analyses are also conducted considering the chemical makeup of the used fuel by radioisotope to understand how those isotopes might migrate through water pathways to the habitable environment post repository closure thousands of years in the future. While the geological barrier is the primary barrier to radioactive release to the habitable environment, as mentioned earlier the “Engineered Barrier System” (EBS) provides multiple barriers as the first line of defense for the natural geological barrier.

Yucca Mountain is designed not only to store commercial used nuclear fuel from many different types of reactors, but also used fuel and nuclear waste from the US nuclear weapons production facilities. Shown on Fig. 11 is an example of the types of waste packages being proposed for disposal.

Modeling these mechanisms for such long durations required developing sophisticated analyses of possible scenarios and likelihood of water migration events (Meecham et al., 2011). This led to the development of probabilistic risk analysis over time periods that span a million years. Due to the uncertainty of such predictions the probabilistic methods are best suited for such analysis. These analyses model degradation mechanisms assuming many different climatic scenarios which can cause possible water intrusion events for thousands of years including uncertainties in data and modeling assumptions.

The models assume that overtime, water will enter the drift, fall on the drip shield eventually failing it thousands of years later. Eventually the water will attack the actual waste canister made of a special alloy material as shown on Fig. 11 after which it will attack the spent fuel pins shown earlier. This process, should it happen as modeled, takes many thousands of years. The EBS is designed to prolong the degradation process. Since water is the primary means of degradation and the pathway to the environment, knowledge of the chemistry of the materials and reactions with water and the isotopic mobility need to be understood and modeled. This understanding, including the underground hydrology, is necessary to predict the pathway to the habitable environment which is the primary concern. Recall that the geologic barrier is the prime barrier to the prevention of radiological releases to the environment.

The Total System Performance Analysis (Sandia National Laboratory, 2008; Department of Energy, 2008) documents the results of thousands of calculations to predict possible releases from the repository over time after repository closure. Each line shows a summary of the collective probabilistic failure analyses under many scenarios postulated to occur including uncertainties of the assumptions used in the analyses. The results are presented as the likelihood of a public radiation exposure over the time period analyzed. Shown on Fig. 12 are the results of the analyses for the 10,000 year licensed period. These results show that expected annual dose to the nearest person is less than 1 mrem per year given all the possible failure modes and uncertainties in modeling. For reference, natural background radiation averages over 250 mrem per year.

Sandia National Laboratory also carried out the analyses to 1 million years to see if there are any radiological outliers. This analysis is summarized in Fig. 13. These results show that the annual expected dose to the nearest individual is less than 10 mrem per year out to 1 million years. Carrying out the analysis to 1 million years, while not required for licensing, shows that even out that long term horizon, the repository and still meet the individual protection standard under many challenging scenarios.

⁴Yucca Mountain receives about 7.5 in. of rainfall per year of which 95% is either evaporated or is taken in by vegetation.

Fig. 10 Considerations Incorporated in the total system performance model. Source: <https://prod-ng.sandia.gov/techlib-noauth/access-control.cgi/2011/118270.pdf>

While analyses over such long times are suspect, the detailed treatment of models, assumptions, input data and uncertainties associated with them provide confidence that the repository will be safe for hundreds of thousands of years. Shown on this plot is the Individual Protection Standard as defined in (Nuclear Regulatory Commission, 2009) which is the NRC requirement for the repository for this time period.

It should be noted that during the loading process and subsequent monitoring period prior to closure, the nuclear waste casks are meant to be retrievable should monitoring results not support expected behavior (Fig. 14) (Sandia National Laboratories, 2008).

A review of the technical findings of the DOE license application by the NRC indicated that they believed that the Yucca Mountain disposal site was acceptable for construction. Anti-nuclear organizations and the state of Nevada filed contentions to be addressed by the NRC Atomic and Safety Licensing Board prior for permission to be granted for construction. Due to the withdrawal of funding by Congress, these hearings were not held leaving the entire question of waste disposal unresolved despite the federal law still requires that Yucca Mountain be the site unless it is found unacceptable for safety reasons.

Gridlock on a solution

Today, there continues to be gridlock on siting repository upon Obama's cancellation of the Yucca Mountain project. The DOE has chosen a "volunteer consensus" siting approach to try to restart the entire process without much success. This decision was based on the recommendation of a "Blue Ribbon" commission. Their report, "Blue Ribbon Commission on America's Nuclear Future, Report to the Secretary of Energy" ([Blue Ribbon Commission, 2012](#)) outlined several actions that need to be taken one of which was volunteer siting. It should be noted that consideration of the Yucca Mountain site was not permitted in this study. To date, no volunteers have come forward for obvious political reason resulting in a situation where the used fuel is currently being stored at existing nuclear plant sites in dry storage or in existing used fuel storage pools under water. To alleviate the problem of removing used fuel from decommissioned nuclear sites and avoid building more dry cask storage facilities at existing nuclear power plant sites, private efforts are now underway in New Mexico and Texas to site consolidated above ground dry cask interim storage facilities which are now going through the licensing process ([Nuclear Regulatory Commission, 2018](#)).

This situation is particularly embarrassing and costly to the taxpayer since taxpayers are paying utilities for storage of the used fuel at the reactor site since under contract, the DOE was obligated to begin taking used fuel by 1998. Thus far, taxpayers have paid US utilities over \$7 Billion which is expected to grow to \$27 Billion assuming that the government takes the spent fuel by 2021 (an unlikely event given progress to date on locating even a temporary storage location for the United States). Industry estimates for the government liability double that to over \$ 50 Billion taxpayer dollars ([Korsnick, 2019](#)).

International status

[Metlay \(2020\)](#) discusses in some detail progress that is being made in other countries in their efforts to dispose of their nuclear waste from their operating plants. The two leading nations in this effort are Finland and Sweden while progress is being made in France, Germany and England. Finland and Sweden have made significant progress. The sites selected were near existing nuclear plants in both countries with public support from local residents and the national government. Each country recognized that they bore the responsibility for disposal of the nuclear waste and assigned private companies (not the government) for managing and disposing the used fuel. The major differences in terms of success between the Finnish and Swedish programs and the United States are that the sites chosen were near nuclear plants so that the residents were familiar with nuclear energy and that the federal government was not responsible for disposal. This decision left national politics out of the picture which has stymied US nuclear waste disposal efforts. Both Sweden and Finland use the same technology and plan to dispose of the spent fuel in a granite geological formation. Since Finland is preparing to open a repository in 2021, it will be briefly described below.

Finland's high level waste repository

Finland produces about 30% of its electricity from nuclear power using 4 reactors. Another nuclear plant is under construction that will increase Finland's nuclear share of electricity production to 60%. The two utilities (Fortum and TVO) operating reactors formed a special company, Posiva, to design, construct and operate the proposed repository ([Posiva, 2019](#)). In 1999 Posiva proposed to the government that the Olkiluoto site be used for what they refer to as a "(very) long-term underground storage facility." The local municipality, Eurajoki, approved the selection which was approved by the national government in 2001. The official name for the repository is "Onkalo." An excavation permit was issued by the municipality after years of site specific study and engineering analysis in 2004. A construction license approved by 2015 with first loading of the nuclear waste is expected by 2023.

The Finnish and Swedish designs call for encapsulation of the used fuel in copper disposal packages to be emplaced in underground granite deposits that have been stable for 9 billion years in a series of tunnels backfilled with an impermeable barrier of bentonite clay. Shown in [Fig. 15](#) are the copper canisters into which the spent fuel will be placed.

The basic repository design calls for a series of underground tunnels cut in granite bedrock as shown in [Fig. 16](#).

The plan is to load the 12 used fuel assemblies in boron steel canister baskets and sealing it in the copper cask. Each cask will be disposed of in its own hole after which it is overpacked with bentonite clay which is designed to keep water from the copper cask. An actual picture of the below ground repository is shown in [Fig. 17](#).

Posiva's license application and safety case was approved by the Finnish regulator STUK in 2015 ([World Nuclear News, 2015](#)). The regulator concluded after the safety review that the repository "can be built to be safe." As opposed to the United States approach where everything needs to be conclusively addressed in the application, the Finnish government has recognized that the process requires a phased approach to licensing in that as more information is learned by the excavation and placement of the waste packages, requirements will be modified as necessary. The safety standards applied by STUK are similar to those applied to nuclear power plants in terms of public health impact. The safety analysis of the repository identifies possible means whereby any of the radioactive materials contained in the waste package should not result in a public exposure no higher than 0.1 millisievert (10 millirem) per year.

Fig. 16 Conceptual design of Finland's nuclear waste repository. Source: http://www.posiva.fi/en/media/image_gallery?gfid_2061=92#gallery_2061.

Fig. 17 Onkolo repository shaft for disposal of copper casks. Source: http://www.posiva.fi/en/media/image_gallery?gfid_2061=92#gallery_2061.

For reference, the average Finnish person (Posiva Safety Case, 2012) is naturally exposed to about 320 millirem per year. Posiva's analysis shows the projected releases to be 10,000 times lower (Posiva Safety Case, 2012).

As in the US case, Finland's and Sweden rely on the same conceptual engineered barrier approach to geological disposal with the geology being the primary barrier to release. The reference time period for the analysis is 250,000 years which should encompass the next ice age (STUX Finnish Regulator, 2016). Although the Finnish approach is considered more deterministic, the analysis does include a risk assessment based on the uncertainties and probability considerations. The expectation is that after 250,000 years, the level of radioactivity remaining is about that of a large uranium deposit.

The regulator and Posiva accept the fact that it is not possible to consider every event that may occur for the 250,000 years but there is high confidence that the multi-barrier and phased approach will be safe for people and the environment. The Onkalo repository is expected to operate for about 100 years after which the access tunnel will be backfilled and sealed.

The estimated cost of the entire Finland's nuclear waste disposal program which is funded by the utilities is about \$ 910 million. The State Nuclear Waste Management Fund which collects the money from the utilities for the nuclear energy generated has about \$1.6 Billion. This is in sharp contrast to the US where the DOE has spent more than \$ 17 billion with not much to show for it.

Public acceptance

Metlay (2020) summarizes the difficulty in public acceptance in many nations including the United States. His conclusions are that there are five reasons for difficulty in siting. They include contested technical claims, public perception of risk and stigma associated with nuclear energy, mistrust, inequitable processes and decision making, and lastly opposition to nuclear power. In the United States, as mentioned previously, politics plays a major role especially in presidential election years.

Summary and conclusions

Nuclear waste can be disposed of safely. While natural analogs provide the best examples of billions of years of confinement in geological media, the best examples found in the United States are the Waste Isolation Pilot Plant in New Mexico, the safety and licensing submittals to the NRC for the Yucca Mountain site, and the Swedish and Finnish licensing applications for an underground repositories. While the US Yucca Mountain Project licensing process was canceled for political reasons, a technical basis exists demonstrating that for 1 million years, far beyond the 10,000 year requirement, that used nuclear fuel can be safely disposed of in an engineered geologic repository. Construction is underway in Finland for a geological repository after safety reviews and the Swedish application is currently undergoing licensing reviews. Siting discussions are underway in France, Switzerland, and Germany.

The extensive US application features a total system performance assessment using probabilistic risk assessment techniques to address potential modeling and input uncertainties for geologic time frames demonstrating that the potential dose to the nearest member of the public over these long times show minimal possible exposures of less than 1–10 millirem per year for the nearest neighbor compared to an annual natural radiation exposure from all sources of 245 millirem for each person for at least 10,000 years. Thus, the safety of the repository can be safely assumed to be acceptable given these results.

Legal and ethical context

At present there is clear and unequivocal understanding that each country is ethically and legally responsible for its own wastes, especially nuclear wastes, therefore the default position is that all wastes will be disposed of in each of the 50 or so countries concerned. McCombie and Chapman (2002) discuss concerns that discussions on shared facilities should not derail national programs then underway. They caution that it is equally important that future development of regional and international projects is not unnecessarily blocked by short-term national considerations. The International Atomic Energy Agency soon published a technical document on the subject (IAEA, 2004).

The main volume of high-level nuclear waste is created in the nuclear power reactors which make electricity in over 30 countries. The elements within the used fuel which make it “waste” are essentially not left-overs from imported uranium—they are created in the operating reactors (by fission and neutron capture). There is thus no moral obligation on uranium suppliers in respect to the wastes, other than that involved in safeguards procedures.

Those International Atomic Energy Agency (IAEA) and bilateral national safeguards procedures track used fuel and its constituents, so any international waste repository has implications under the Nuclear Non-Proliferation Treaty (NPT). The trustworthiness and standing of the host country is fundamental to the project’s acceptability to NPT states, which comprise virtually every country but India, Pakistan, Israel and North Korea.

Also, the international treaty produced by IAEA and signed by most nations of the world in 1997 covering the management and disposal of used fuel and high-level wastes requires that the host facility or system meets the highest national and international standards.

There are over 20 countries with no nuclear power that have need for secure disposal of long-lived radioactive wastes from their research reactors, or from nuclear medicine or other technology.

International repository concepts

In November 2003, Dr. Mohamed ElBaradei, Director-General of the UN’s International Atomic Energy Agency (IAEA), said to the UN General Assembly: “We should ... consider multinational approaches to the management and disposal of spent fuel and radioactive waste. Over 50 countries currently have spent fuel stored in temporary locations, awaiting reprocessing or disposal. Not all countries have the appropriate geological conditions for such disposal—and, for many countries with small nuclear programs, the financial and human resources required for the construction and operation of a geological disposal facility are daunting.”

In a later article he specifically included research reactors in the scope of this suggestion and concluded that “considerable advantages—in cost, safety, security and non-proliferation—would be gained from international co-operation in these stages of the nuclear fuel cycle.” These principles are expressed in IAEA (2004) and an expert group report to him followed up on this (IAEA, 2005).

Nearly 25 years earlier, in 1980, the IAEA-sponsored International Nuclear Fuel Cycle Evaluation (INFCE) waste management and disposal report had firmly recommended that proposals “for establishing multinational and international repositories should be elaborated” due to their non-proliferation advantages. “Centralised facilities for disposal of spent fuel and/or vitrified high-level wastes ... would reduce the diversion risk” and be more economical.

Individual waste repositories for spent nuclear fuel and other high-level wastes need to be reliably secure. Achieving high security means:

- They can make a vital contribution to global environmental *safety* by ensuring that radioactive substances are permanently removed from the human environment,
- They can greatly enhance global *security* in the broader sense by preventing malicious use of fissile and radiological materials.

Insofar as these functions are less than fully assured in any of the 50 countries concerned with radioactive wastes, there is justification for some kind of international collaboration and facilities, possibly on a regional basis. In particular, the second point is arguably best achieved by international collaboration under IAEA auspices. McCombie and Chapman (2004) present arguments that the international community should take concrete steps to expedite credible proposals for shared repositories.

In 2004 the IAEA (IAEA, 2004) put forward three concepts for multinational repositories:

- Incremental addition to a large national program
- A supra-national facility with international management and control
- Collaborative partnering among countries for a multinational repository.

While most countries should be able to find suitably safe sites in stable geological formations, demonstrating this safety so as to create public confidence is best achieved where there is simple geology.

Certainly, there is wide consensus that geological disposal is the only way of ensuring adequate safety and security in the long-term management of used fuel which is treated as waste, and also of separated high-level radioactive wastes which, if recycling of actinides becomes established, eventually will be mainly fission products (Greeneche, 2021; Wigeland and Taiwo, 2021).

While acknowledging each country's responsibility for its own wastes, the limits to the logic on indigenous disposal can be seen from the changing national borders within Europe over the last century. For Slovenia for instance (which has one nuclear power reactor), its capital city Ljubljana has politically lain within seven different states in the last hundred years or so.

The South Australian Royal Commission into the Nuclear Fuel Cycle (2016) report notes that:

There are international models that address the transfer of waste between countries. The Basel Convention, which applies to hazardous wastes other than radioactive waste, imposes requirements upon the transfer of hazardous wastes between countries; namely the transfer shall only take place where prior informed consent has been received and only if the transfer represents an environmentally sound solution. Hazardous wastes are commercially transferred under this regime. While the Joint Convention applies equivalent requirements to transfers of radioactive waste between countries, there are no operating models for the commercial transfer of used fuel for disposal.

Various organisations have looked into potential concepts. There are, however, commercial models for the transfer of used fuel between countries for reprocessing, as well as the take-back of fuel from reactors built by Rosatom, the Russian state nuclear corporation. The United Kingdom has reprocessed used fuel for many countries but does not accept the waste products for disposal. In all cases, transfers can only take place if the recipient country has the capacity to manage the waste safely and where such transfer has been agreed between the countries concerned.

In October 2016 the *reliable nuclear fuel services* working group of the International Framework for Nuclear Energy Cooperation (IFNEC, 2016) released a position paper: *Overview of the Dual Track Approach for National Back-end Programs*, focused on the needs of countries with small nuclear programs. It was based on previous work initiated by Arius as well as studies done by IAEA and NEA. It notes that under the IAEA Joint Convention on wastes and spent fuel, contracting parties have agreed that the country that discharges the spent fuel and receives the benefits of the power generated bears the responsibility for its management, including disposal. Since disposal is a relatively major burden with small quantities, due to high fixed costs, some international collaboration is suggested. This is the dual track beyond simply national approaches, allowing a country to offer repository facilities as a service provider.

This was fleshed out in an IFNEC (2019) presentation to the IAEA in mid-2019: *Development of Multinational Repository Concept: Exploring Alternative Approaches to Financing Multinational Repository*. This reported on an IFNEC workshop held in Paris in 2018 which considered the spending profile on a repository from siting and licensing, through construction (35% of total), operation (45% of total) and closure. It concluded however that multinational repository development was not yet timely, though the concept had potential and should continue to be studied. Countries with small nuclear programs should set aside funds in anticipation. IFNEC should continue to work on linking any potential service provider with potential customer countries.

South Australian proposal

In May 2016 the South Australian Royal Commission into the Nuclear Fuel Cycle reported. A major recommendation was that a facility for the disposal of international used nuclear fuel and intermediate-level waste should be established in South Australia. It found that the state "has the necessary attributes and capabilities to develop a world-class waste disposal facility, and to do so

safely” as a service provider. Based on a “cautious and conservative approach,” from assessments of used fuel inventories and potential global interest the commission determined that such a facility could generate more than A\$ 100 billion in income in excess of expenditure (including a reserve fund of A\$ 32 billion for facility closure and ongoing monitoring) over the 120-year life of the project.

The World Nuclear Association said that the report had “fundamentally changed the nature of the global nuclear waste discourse,” and a multi-national waste facility based in South Australia would provide a welcome option for many countries operating nuclear facilities today. It would be a “viable alternative” to national projects. Such a large multi-national waste storage facility and repository would be a world-first and should offer advantages in terms of siting and economics when compared with smaller national approaches.

The [South Australian Royal Commission into the Nuclear Fuel Cycle \(2016\)](#) report continues:

Under the Joint Convention on the Safety of Spent Fuel Management and the Safety of Radioactive Waste Management, any proposal to store and dispose of used fuel in South Australia would require agreement between the countries concerned. In Australia, treaty level agreements would need to be developed between the federal government and the relevant overseas government. An agreement would also need to specify arrangements between the Australian Government and the Government of South Australia, to ensure these commitments were fulfilled. Further agreements may be required with third party countries: for example, if they have supplied uranium to the country wishing to store and dispose of used fuel in South Australia.

As Australia is a net exporter of energy, it has a significant role to play in assisting other countries to lower their carbon emissions. This includes countries with less opportunity for large scale renewable energy deployment than Australia, for whom nuclear power makes a substantial contribution to their production of low-carbon energy. For new nuclear entrants or countries with little prospect of siting their own used fuel disposal facilities, an international solution would remove a significant impediment to the new or ongoing use of nuclear power as a low carbon technology. As a result, Australia would derive a reputational and financial benefit by hosting a facility for the disposal of international used fuel.

Excluding countries which are committed to developing national solutions or already have structured programs leading to a domestic facility, and those with laws prohibiting export of wastes, the report identifies 90,000 tonnes of used fuel and almost 270,000 cubic metres of intermediate-levels wastes as a potentially accessible market and available for an Australian repository today. These amounts, comprising about one quarter of actual world used fuel and ILW, are increasing annually. By 2090 the amounts are 276,500 tonnes and 782,000 m³ respectively. The viability analysis is based on half these amounts.

Based on detailed analysis, the Royal Commission considers that a reasonable baseline price for the purpose of assessing viability would be A\$ 1.75 million/tHM for used fuel. This is based on a reasonable baseline “willingness to pay” estimate of A\$ 1.95 million/tHM, less A\$ 0.2 million/tHM to account for costs incurred by customers in preparing and delivering the waste to South Australia.

Regarding intermediate-level wastes, the [Royal Commission into the Nuclear Fuel Cycle \(2016\)](#) report says:

The management and disposal of intermediate level waste commands a far lower willingness to pay than for used fuel since it is more readily managed and stored.

However, a 2011 report from the UK Department of Energy and Climate Change has suggested that £25 900 per m³ (in current terms, A\$66 000 per m³) represents a levy that ought be imposed on nuclear power plant operators to reflect current costs and the potential for future increases. In the interests of conservatism, and to address the costs of packaging and transport (which are not as well defined as for used fuel) a price to charge of A\$40 000 per m³ is considered appropriate for the purposes of a viability analysis.

Interim above-ground storage for used fuel inside heavily engineered, purpose-built casks would be followed by deep geological disposal, the repository design based on that under construction at Olkiluoto in Finland at 400–450 metres depth. In the analysis, the geological disposal facility for used fuel is notionally co-located with an intermediate level waste facility, where those packages are placed in medium-depth vaults of 50–250 metres. The report said that integrated facilities with capacity to store and dispose of used fuel would be viable.

On a number of realistic scenarios, such a facility would be highly profitable. The timeline for establishing an interim storage facility and associated transport infrastructure, including harbor, port and railway would be 11 years after project commencement. Transferring used fuel and ILW from surface storage to underground repository would begin at 28 years. Revenue would thus commence at year 11, based on 3000 t/year used fuel, so \$5.25 billion/year over 30 years from then simply for the fuel. Total capital cost would be \$41 billion over some years including 25% contingency, and operating expenses from year 11 about A\$ 0.878 million (\$ 2015). Overall total revenue (in undiscounted terms) would be more than A\$ 257 billion, with total costs of A\$ 145 billion. The project would add 4.7% to gross state product and 1.9% to employment by 2030.

ARIUS and Europe—ERDO

Early in 2002 a new, non-commercial body to promote the concept of regional and international facilities for storage and disposal of all types of long-lived nuclear wastes was set up. This is ARIUS—the Association for Regional and International Underground Storage. A key objective is to explore ways of providing shared radioactive waste management approaches and facilities, in particular storage and disposal facilities for smaller users. Membership is open and comprises countries with small nuclear programs as well as industrial organisations with relevant interests. Arius is a successor to the Pangea proposal (see below).

Arius focused initially on Europe, and the feasibility of regional repositories there. In 2002 a European Commission Directive said that geological disposal of radioactive wastes was preferred and that “A regional approach, involving two or more countries, could also offer advantages especially to countries that have no or limited nuclear programs, insofar as it would provide a safe and less costly solution for all parties.”

In mid-2003 Arius initiated the SAPIERR Pilot Project for European Regional Repositories, which obtained European Commission approval. This was undertaken over 2 years to 2005 to help the EC grapple with the regional repository issue as flagged earlier in the EC Radioactive Waste Directive. It allowed potential options for regional collaboration and for regional repositories to be identified, though it did not extend to site identification. Slovakia provided the project coordination.

Following this pilot study, in September 2006 a new EC-funded SAPIERR (Strategic Action Plan for Implementation of European Regional Repositories) project to assess the feasibility of European regional waste repositories was commenced, indicating a recognition in the EU that implementing 25 national repositories is not optimal economically or for safety and security. The project was in line with proposals from the International Atomic Energy Agency (IAEA), Russia and the United States (with GNEP, now IFNEC) for multilateral cooperation in the fuel cycle in order to enhance global security. Shared repositories for high-level nuclear wastes are an important element of this.

The SAPIERR project held its final symposium January 2009 in Brussels. The results of studies on the viability of shared, regional European geological repositories were presented to 50 participants from 21 countries. The aspects considered included organisational and legal issues, economic impacts, safety and security considerations, and public and political attitudes to multinational repositories (McCombie, 2009).

The main outcome of this was that 14 countries¹ resolved to move towards setting up a European Repository Development Organisation (ERDO). The first step in the strategy was the establishment of a self-financing Working Group (ERDO-WG) of interested countries in 2009 to prepare a consensus model to be agreed for ERDO, using the SAPIERR findings as a starting point (see www.erdo-wg.eu). It proposes a sister organisation to waste agencies from European countries that have opted for a purely national repository program. This model was presented to potentially interested countries, and internal discussions are still in progress in several of these on adopting the multinational solution as one option when responding to the requirements placed on EU Member States by the EC Waste Directive of 2011.² Some member states have already decided to follow this course. The ERDO-WG secretariat is provided by ARIUS, Switzerland, and the administration by the Netherlands waste agency, COVRA (<https://covra.nl/en/disposal/international>).

ARIUS: The Persian Gulf and SE Asia

Alongside ERDO, Arius is evaluating whether similar, regional shared solutions would be appropriate for and of interest to emerging nuclear power programs in the Gulf, Middle East and North Africa (MENA) region and also SE Asia. The overall aim is to assess the interest within each region of working towards Regional Repository Development Organizations (RDOs) similar to the Europe’s ERDO. A scoping study was completed in 2011 and funding for a further two-year project was awarded in mid-2011 by two US Foundations. In 2011 the UAE’s permanent representative to the IAEA raised the possibility of a regional repository and said that “Among GCC countries there is potential for a lot of co-operation in this area, including waste management and waste disposal.” A final project report from the scoping study was in February 2016.

¹Austria, Bulgaria, Czech Republic, Denmark, Estonia, Ireland, Italy, Latvia, Lithuania, Netherlands, Poland, Romania, Slovakia, and Slovenia, though some subsequently did not continue in the ongoing ERDO-WG. In April 2020 the WG active membership comprised Austria, Croatia, Denmark, Italy, Netherlands, Norway, Poland and Slovenia.

²At the end of 2011, the ERDO Working Group, led by representatives of the Dutch and Slovakian national programs, prepared a set of documents outlining the possible structure, operating methods and financing options for a formal, multinational, European waste management agency (the ERDO). These documents were submitted to all EU governments that might be interested in actively participating in the preparation of this next step, and also provided as information to those European countries, such as Sweden, Finland and France, that have decided on purely national approaches to managing their radioactive wastes. Discussions with potential participants have been underway since 2012, and a number of positive responses received. In December 2013 the EC, the European Nuclear Energy Forum (ENEF) Waste Group and the ERDO-WG organised a meeting in Luxembourg to consider how to help all EU member states meet the requirements set by the EC Waste Directive of 2011. The meeting addressed the fact that some EU member states are not well equipped to meet Waste Directive targets, but could develop a common program for addressing many of its requirements. This led in June 2014 to a presentation to the European Parliament Working Party on Atomic Questions on the COMS-WD (Cooperation between Member States Responding to the Waste Directive) proposal. http://www.erdo-wg.eu/Documents_files/COMS-WD.pdf. In September 2014 Arius together with European partners submitted the COMS-WD proposal to the €80 billion Horizon 2020 EU research and innovation program. Nine EU countries (Austria, Croatia, Denmark, Greece, Italy, Netherlands, Poland, Portugal, and Slovenia) and the Joint Research Centre Institute for Transuranium Elements (JRC-ITU) were involved with Arius in this. JRC-ITU involvement is to ensure continued cooperation with other EU projects. However, the proposal was rejected as being “out of scope” for Horizon 2020. Nevertheless, the multinational or dual-track option is being included by some countries in their strategies responding to the Waste Directive—Netherlands and Slovenia so far.

In April 2012, an initial meeting took place in Abu Dhabi, hosted by the Federal Authority for Nuclear Regulation (FANR) of the United Arab Emirates (UAE) and supported by the IAEA. Around 35 participants attended, primarily from UAE waste management and planning organisations. UAE was an obvious host for a first meeting since it has the most advanced nuclear power program in the region and has also formally committed to a “dual track” radioactive waste management strategy that involves developing a national storage and disposal program in parallel with exploring regional cooperation options. A follow up to the Abu Dhabi meeting was in November 2012 in Tunisia, hosted by the Arab Atomic Energy Agency (AAEA), with a widened group of participating MENA countries. In the six countries comprising the Gulf Cooperation Council region, which includes two nations with expanding nuclear power programs (the UAE and Saudi Arabia), consideration is also being given to launching a joint project on the feasibility of shared storage and/or disposal facilities. Further discussion has followed, including at a January 2015 workshop in Abu Dhabi.

Arius estimated that the cost of such a shared regional repository in the Middle East might be \$4 billion, but would offer a large payback in the form of regional security. It would not be needed before about 2080.

The European and MENA initiatives will act as role models for a possible SE Asian initiative, where interest has been shown by representatives of potential nuclear power newcomer nations such as Malaysia and Vietnam and where involvement with the mature nuclear power programs of the region (e.g. in the Republic of Korea and Taiwan) would add an extra dimension to the issue. Following a January 2014 meeting in Indonesia, further meetings are envisaged.

An EU group, the Implementing of Geological Disposal of Radwaste Technology Platform (IGD-TP) was established in 2009 by several EU organisations to support research related to its vision and assist the various EU programs. It does not have government-level representation but is partly funded by the EU.

Fuel leasing

There have been a number of proposals for fuel leasing. At present the normal process is that a utility buys uranium from a mining company, then gets it converted, enriched and fabricated, before using it and discharging the used fuel. That used fuel becomes the responsibility of the country in which it has been used, as outlined in the first paragraphs of this article.

Fuel leasing is an alternative concept whereby the utility leases its fabricated fuel from a supplier, probably in another country, and after it has been used that supplier takes it back. This concept is not yet in use except for some very limited applications, mainly for Russian-built nuclear power plants in NPT non-weapons states (e.g. Bangladesh, Turkey, Iran). The supplier would then add the leased used fuel to its own larger stocks to be stored for later disposal or reprocessing and recycling, in which case the valuable components would belong to the fuel supplier/leaser.

The concept was part of the Global Nuclear Energy Partnership (now IFNEC) launched in 2006, in order to restrict the spread of sensitive technologies such as enrichment, but it did not come to fruition under that program. Of all the nuclear suppliers, Russia has expressed the most support for fuel leasing and take-back. Russia's fuel supply contract with Iran involves leasing, and Iran is required to send the used fuel back to Russia. Russian law allows import of foreign used fuel for reprocessing and the return of wastes (as with reprocessing other countries' used fuel in France and Britain), and Russia's default position in supplying reactors to non-nuclear weapons states is to take back Russian-origin fuel without requiring return of the wastes to those countries, as with Iran.

The Pangea proposal

In the 1990s Pangea Resources, a UK-based company, identified Australia, southern Africa, Argentina and western China as having the most appropriate geological credentials for a deep geologic repository, with Australia being favored on economic and political grounds. It would be located where the geology has been stable for several hundred million years, so that there need not be total reliance on a robust engineered barrier system to keep the waste securely isolated for thousands of years.

It would be a commercial undertaking and would have dedicated port and rail infrastructure. It would take spent fuel and other wastes from commercial reactors, and possibly also material from weapons disposal programs.

Pangea summed up the situation thus:

By taking a fresh look at the reasons for the difficulties which have faced most national repository programs, and discarding the preconception that each country must develop its own disposal facilities, it is possible to define a class of simple, superior high-isolation sites which may provide a multinational basis for solving the nuclear waste disposal problem.

The relatively small volumes of high-level wastes or spent fuel which arise from nuclear power production make shared repositories a feasible proposition. For small countries, the economies of scale which can be achieved make the concept attractive. For all countries, objective consideration of the relative merits of national and multi-national solutions is a prudent part of planning the management of long-lived radioactive wastes.

Early in 1999 Pangea Resources released its project proposal to the Australian public, expecting this “to initiate discussions which will enable us to more fully assess the feasibility and strategy of our proposal ... on (its) merits.”

Pangea’s objectives were to site a deep geologic disposal facility in a region where the geology and biosphere conditions meet the test of simplicity coupled with robustness in order to demonstrate that the performance of the facility from a safety standpoint will meet the highest international standards and international safeguard requirements. In addition to its ideal geological characteristics, the host country should preferably be a first-world, stable democracy, familiar with high-technology enterprises.

Pangea’s strategy implied that the geological barrier can be the primary safety barrier, in contrast to some other potential repository concepts where the waste form and the engineered barriers are required to be more dominant. There is a side benefit in that less complex and less expensive engineered barriers may be sufficient. Pangea also saw a potential public acceptance benefit, in that reliance on a simple geological barrier might be more readily understood and accepted.

The Pangea concept envisaged a dedicated port and rail link to an inland repository site covering perhaps 5 km² on the surface and 20 km² underground (500 m down). There would be a fleet of 35 dedicated and purpose-built ships at any one time.

Pangea’s business plan was based on taking 75,000 t of spent fuel and high-level waste from reprocessing spent fuel, plus some intermediate-level wastes from decommissioning nuclear facilities, over some 40 years. Spent fuel would be shipped to the facility at a rate of about 2000–3000 t per year once it was fully operational. This rate is about 20% of the spent fuel generated annually by commercial reactors around the world, or to put it another way, the repository is designed to take 25% of the world’s civil waste inventory at the time it opens. The projected size of the repository is thus similar to that proposed at Yucca Mountain, Nevada.

The capital cost was estimated at US\$ 6 billion, with some US\$ 400 million per year operating cost. An Access Economics study projected total export revenues over 40 years of about US\$ 100 billion, with payments to governments of about \$50 billion (1998 dollars) before considering multiplier effects. This would have added about 1% to the Australian GNP. The project envisaged establishment of a shipyard and foundry for the manufacture of 70 specialized ships and some 3000 large stainless steel transport casks as well as port and fleet maintenance facilities. Direct employment would be about 2000, indirect about 6000 people.

While the concept aims at nuclear waste generated by countries other than the United States, that country would need to be closely involved because through Non-Proliferation Treaty provisions, it controls some 60% of the nuclear fuel worldwide and would have to authorize any international movement of it.

The commercial scheme would also provide the repository which could be used to dispose of unwanted nuclear materials from disarmament, which was seen as a major spin-off. These would include excess plutonium from nuclear weapons either in spent mixed oxide fuel or in the Synroc-based ceramic developed by the Australian Nuclear Science & Technology Organisation (ANSTO) and chosen in 1998 by the US Department of Energy as the wasteform to immobilise some of its excess weapons plutonium (see link at end).

The initial response from the federal government however was to reiterate Australia’s long-standing and bipartisan policy of not importing nuclear wastes and saying that there was no immediate intention of considering such a proposal. Then, after only cursory consideration, the Western Australian parliament passed a Bill to make it illegal to dispose of foreign high-level waste in the state without specific parliamentary approval. Pangea continued its geological investigations in that state while extending its feasibility study to other potential host regions.

The Pangea concept can be traced to the Synroc Study Group, which began its activities in 1988, set up by the Australian government to study the commercial potential for Synroc in a global context. It was conducted by four leading Australian resource companies, assisted by ANSTO and the Research School of Earth Sciences at the Australian National University.

Russian plans 2001–06

In 2001 the Russian parliament (Duma) passed legislation to allow the import of spent nuclear fuel. The President signed this into law and set up a special commission to approve and oversee such imports. The commission would have 20 members, five each from the Duma, the Council (upper house), the government and presidential nominees. It would be chaired by Dr. Zhores Alferoy, a parliamentarian who is also Vice President of the Russian Academy of Sciences and a Nobel Prize physicist.

This scheme was progressed in 2005 when the Duma ratified the Vienna Convention on civil liability for nuclear damage. However in July 2006 Rosatom announced it would not proceed with taking any foreign-origin used fuel.

In 2003 Krasnokamensk had been suggested as the site for a major spent fuel repository—it is a city 7000 km east of Moscow in the Chita region and is a center for uranium mining and milling. [McCombie and Chapman \(2005\)](#) discuss Krasnoyarsk’s potential. Then in 2008 the Nizhnekansky Granite Massif at Zheleznogorsk in Krasnoyarsk Territory was put forward for a national deep geological repository. In August 2016 the Territorial Planning Scheme to 2030 confirmed the site and approved construction of repository facilities here for 4500 m³ net of class 1 wastes and 155,000 m³ net of class 2 wastes.

(Russia continues to take back for reprocessing all fuel that it supplies in connection with reactors that it builds in foreign countries other than India.)

Summary

International waste repositories are a logical development for countries with a relatively small amount of high-level wastes. However, working through the political implications for potential host countries is not straightforward.

INDEX

Notes

Cross-reference terms in *italics> are general cross-references, or refer to subentry terms within the main entry (the main entry is not repeated to save space). Readers are also advised to refer to each article for additional cross-references – not all of these cross-references have been included in the index cross-references.*

The index is arranged in set-out style with a maximum of three levels of subheading. Major discussion of a subject is indicated by bold page numbers. Page numbers suffixed by t, f, and b refer to Tables, Figures, and Boxes respectively. *vs.* indicates a comparison.

The index entries are presented in word-by-word alphabetical sequence in which a group of letters followed by a space is filed before the same group of letters followed by a letter. For example, entries beginning 'air density' are alphabetized before 'aircraft.' Prefixes and terms in parentheses are excluded from the initial alphabetization.
